One of the most basic of these social skills is the ability to engage in sustained, responsive interactions with peers. These interactions require cooperation, sharing, and taking turns—behaviors that first appear in the preschool years. A second social skill that children learn is the ability to detect and correctly interpret other people's emotional signals. Much as children's school performance depends on processing academic information, their social performance depends on processing information about other people (Slomkowski & Dunn, 1996). A related set of social skills involves the ability to feel what another person is feeling, or something close to it (*empathy*), and to respond with comfort or help if the person is in distress. Children who understand another person's perspective, who appreciate how that person might be feeling, and who behave accordingly tend to be the most popular members of their peer group (Izard et al., 2001; Rubin, Bukowski, & Parker, 2006). Children who do not have these skills are rejected or neglected; they may become bullies or the victims of bullies.

Parents can help their children develop social skills by engaging them in lots of "pretend" play and other prosocial activities and by encouraging them to express their emotions constructively (Eisenberg et al., 2006; Ladd, 2005). Affectionate mothers who discuss emotions openly and who provide clear messages about the consequences of their child's hurtful behavior effectively encourage the child to be empathic (Eisenberg, 1997). In contrast, children who have been abused by their parents tend to lack important interaction skills and are thus more likely to be victimized by their peers (Bolger & Patterson, 2001). Older siblings can help children develop social skills by acting out social roles during play and by talking about their feelings (Ruffman et al., 1998). Teachers' ratings suggest that children with siblings tend to have better social skills than those without sibs (Downey & Condron, 2004). And those who have closer relationships with siblings also tend to develop better relationships with peers (Kim et al., 2007).

The ability to control one's emotions and behavior—an ability known as **self-regulation**—is another social skill that develops in childhood (Rothbart & Bates, 2006; Thompson, Lewis, & Calkins, 2008). In the first few years of life, children learn to calm or console themselves by sucking their thumbs or cuddling their favorite blanket (Posner & Rothbart, 2000). Later they learn more sophisticated strategies of self-regulation. These include waiting for something they want rather than crying or grabbing for it (Eisenberg et al., 2004), counting to ten in order to control anger, planning ahead to avoid a problem (e.g., getting on the first bus if the school bully usually takes the second one), and recruiting social support (e.g., casually joining a group of big kids to walk past the bully on the playground). Children who cannot regulate their emotions tend to experience anxiety and distress and have trouble recovering from stressful events. They become emotionally overaroused when they see someone in

self-regulation The ability to control one's emotions and behavior.

distress and are often unsympathetic and unhelpful (Eisenberg et al., 2006). Further, boys whose emotions are easily aroused and have difficulty regulating this arousal become less and less popular with their peers and may develop problems with aggressiveness (Eisenberg et al., 2004, 2009; Fabes et al., 1997; Spinrad et al., 2007).

FOCUS ON **RESEARCH METHODS**

Exploring Developing Minds

Children's ability to develop social skills depends partly on their ability to understand other people's behavior and the thinking that might be behind it. Critical to this understanding is the recognition that other people's thinking might differ from our own and that the other person's actions might be based on incorrect information. For more than two decades, researchers have argued that children under 4 years of age cannot understand other people's mental states because they do not yet have a "theory of mind."

This argument was based on studies that asked children questions about other people's beliefs (e.g., Baron-Cohen, Leslie, & Frith, 1985). In one study, children were brought to a laboratory one at a time and shown a simple little drama starring two dolls, "Sally" and "Anne." First, Sally puts a marble in her basket and then leaves the stage. While Sally is away, Anne takes the marble out of Sally's basket and puts it into her own box. Then Sally returns to get her marble, and each child is asked where Sally will look for her marble. To correctly predict that Sally will look in the basket where she last saw the marble, the children would have to recognize that Sally has a false belief about its location. Even though they know where the marble really is, they will have to be able to "read Sally's mind," realize what she must be thinking, and say, "Sally will look in her basket." However, most children under the age of 4 ignore the fact that Sally thinks the marble is still in her basket and say that she will look in Anne's box.

What was the researcher's question?

Renee Baillargeon (pronounced "by-ahr-ZHON") wondered, though, whether the inability of these young children to recognize what others are thinking reflected a true lack of a "theory of mind" or was the result of using research methods that were not sensitive enough to detect its existence. So her research question was whether more specialized research methods might reveal that even children under 4 can understand that the behavior they see in others is affected by the other people's mental states, including false beliefs and false perceptions.

How did the researcher answer the question?

Instead of requiring children to answer questions about other people's behavior, Baillargeon used a potentially more sensitive method to probe young children's knowledge. Specifically, she showed infants various events and then carefully measured the amount of time they spent looking at them. She reasoned that infants' tendency to look longer at certain events indicates that those events violate their expectations about the world.

Baillargeon used this method to measure the ability of 15-month-old infants to predict where a woman would look for a toy, depending on whether she had a true or a false belief about the toy's location (Onishi & Baillargeon, 2005). Each infant first watched the woman play with a toy watermelon slice for a few seconds and then hide it inside a green box. Next, the woman watched the toy being moved from the green box to a yellow box. Then she left the scene, and while she was gone, the toy was put back into the green box. When she came back, she looked for the toy by reaching into either the green box or the yellow box.

Baillargeon reasoned that if the infants expected the woman to search for the toy on the basis of her false belief that it was still in the yellow box, they would look longer at her if she violated their expectation by searching in the green box instead. This longer looking would convey the message "Hey, how could she know the toy had been moved? I expected her to look where she last saw it!" But if, as earlier studies had found, the infants really had no "theory of mind," they would ignore the woman's false belief and expect her to look in the green box, where they knew the toy now lay. If she met this expectation, they would not pay any special attention to her action.

What did the researcher find?

The results of this study showed that contrary to what would be expected from previous research, the infants looked reliably longer when the woman searched for the toy in the green box.

What do the results mean?

These results support the view that despite lots of earlier research evidence to the contrary, infants under the age of 4 do have a "theory of mind." When evaluated using the right kinds of research methods, these children demonstrate an ability to recognize that other people have beliefs and perceptions that can be false, that those beliefs and perceptions can differ from the child's own, and that these mental states affect the other person's behavior.

What do we still need to know?

Among other things, it would be good to know more about the extent of infants' understanding of mental states. Does it appear in other situations? Baillargeon has conducted a series of studies to begin to explore this question (Song & Baillargeon, 2008). In one of these, infants viewed a scene in which a woman looked for a doll with blue pigtails. She could look either in a plain box or in a box that had a blue tuft of hair sticking out from under its lid. The infants knew that the doll was in the plain box, but they stared longer when the woman looked in that box first; this meant that they expected her to be misled by the blue tuft of hair and to falsely perceive it as belonging to the doll. In another study, Baillargeon investigated whether infants know that new information can correct an adult's false belief (Song et al., 2008). In this case, infants saw an adult hide a ball in a box while another adult watched. After the first adult left the scene, the second adult moved the ball from the box to a cup. When the first adult returned, the second adult told her, "The ball is in the cup!" Infants stared longer if despite this corrective information, the adult searched for the ball in the box. Those who saw her reach for the cup did not pay special attention, suggesting that the infants expected her to do so once her false belief had been corrected. What mental states besides beliefs and perceptions can infants understand? Do they also realize that other people's behavior can be influenced by goals, intentions, emotions, and even the fairness or unfairness of a situation? How soon after birth does a "theory of mind" develop? These are among the dozens of additional questions that remain for future research in this fascinating area of developmental psychology (Woodward, 2009).

Gender Roles

LINKAGES Who teaches boys to be men and girls to be women? (a link to Learning, p. 220)

Another important aspect of understanding other people and being socially skilled is knowing about social roles, including **gender roles**, also known as **sex roles**, which are the general patterns of appearance and behavior associated with being a male or a female. Gender roles appear in every culture, but they are more pronounced in some cultures than in others. One analysis revealed, for example, that where there are smaller male-female differences in social status, gender role differences are smaller too (Wood & Eagly, 2002). Research by Deborah Best (1992; Williams & Best, 1990) suggests that children show gender role expectations earliest in Muslim countries (where the differences in roles are perhaps most extreme), but children in all twenty-five countries she studied eventually developed them. In North America, some aspects of traditional gender roles are weakening. For example, men today are less likely than they were in the 1970s to describe themselves as "tough" and "aggressive" (Spence & Buckner, 2000). And one sample of students in counseling psychology defined a mentally healthy woman as independent and ready for a challenge—traditionally

gender roles (sex roles) Patterns of work, appearance, and behavior that a society associates with being male or female.

masculine traits—as well as nice and nurturing, which are traditionally feminine characteristics (Seem & Clark, 2006). When it comes to occupations, though, most traditional gender stereotypes remain (Liben & Bigler, 2002). Both children and adults still think of doctors, dentists, mechanics, pilots, plumbers, truck drivers, firefighters, electricians, architects, police officers, and engineers as male and think of librarians, nurses, teachers, secretaries, dancers, hairdressers, and decorators as female (Kee et al., 2005; Oakhill, Garnham, & Reynolds, 2005).

Gender roles exist because they are deeply rooted in both nature and nurture. Small physical and behavioral differences between the sexes are evident early on (Eagly, 1996). Girls tend to speak and write earlier and to be better at grammar and spelling than boys (Halpern, 1997). Girls are more attracted than boys are to baby faces (Maestripieri, 2004), and by 4 months of age, the average duration of mutual gazing between girls and women is four times longer than that between boys and women (Leeb & Rejskind, 2004). Girls are able to read emotional signals at younger ages than boys can, and by school age, they are likely to be more sensitive, kind, considerate, and empathic (Rose & Rudolph, 2006). They are more emotionally responsive to others and more likely to ask for help as well as to offer it (Benenson & Koulnazarian, 2008; Bornstein et al., 2008). They can also control their emotions better than boys can (Else-Quest et al., 2006). Girls engage in more social conversation and self-disclosure with their friends, and they care more about their friendships than boys do (Rose & Rudolph, 2006).

Boys, in contrast, tend to be more skilled than girls at manipulating objects, constructing three-dimensional forms, and mentally manipulating complex figures and pictures (Choi & Silverman, 2003; Newhouse, Newhouse, & Astur, 2007). They are also more physically active. They play in larger groups and spaces and enjoy noisier, more strenuous physical games (Fabes, Martin, & Hanish, 2003; Rose & Rudolph, 2006). From the age of 2, boys engage in riskier behaviors and are injured at a rate that is two to four times that of girls (Morrongiello & Hogg, 2004). On the playground, boys are the overtly aggressive ones; they push and punch each other more than girls do (Baillargeon et al., 2007; Card et al., 2008; Ostrov, 2006). They are more competitive and more concerned with dominance than with friendship (Rose & Rudolph, 2006). Girls are more likely to use "relational" or "social" aggression than physical aggression; they hurt with gossip and threats to withdraw friendship rather than with sticks and stones (Crick et al., 2004).

Biological Factors in Gender Roles A biological contribution to these male-female differences is suggested by several lines of evidence. First, studies show sex differences in anatomy, hormones, and brain organization and functioning that are related to sex-typed patterns of behavior (Auyeung et al., 2009; Geary, 1999; Ruble, Martin, & Berenbaum, 2006). Second, cross-cultural research reveals consistent gender patterns at an early age, even in the face of differing socialization practices (Baillargeon et al., 2007; Simpson & Kenrick, 1997). Third, research with nonhuman primates finds sex differences that parallel those seen in human children. Young female animals prefer playing with dolls, and young males prefer playing with a toy car, for example (Alexander & Hines, 2002; Williams & Pleil, 2008). Fourth, research in behavioral genetics shows that genes exert a moderate influence on the appearance of gender-typed behaviors (Iervolino et al., 2005).

Socialization of Gender Roles There is no doubt, though, that gender roles are also influenced by socialization, partly by exaggerating whatever biological gender differences may already exist (Hyde, 2005, 2007). From the moment they are born, boys and girls are treated differently. Adults usually play more gently and talk more to infants they believe to be girls than to infants they believe to be boys. They shower girls with dolls and doll clothes, boys with trucks and tools. They encourage boys to achieve, compete, explore, control their feelings, be independent, and assume personal responsibility. They encourage girls to be reflective, dependent, domestic, obedient,

Learning Gender Roles

and unselfish (Ruble, Martin, & Berenbaum, 2006). They speak with more feeling to girls and in more supportive ways (Kitamura & Burnham, 2003; Leaper, Anderson, & Sanders, 1998) and are harsher with boys (McKee et al., 2007). When asked to imagine that their child has been injured, parents are more concerned about even minor injuries to daughters than to sons (Morrongiello & Hogg, 2004). They are also more likely to stop a fight between their children when a daughter is involved (Martin & Ross, 2005). In these and many other ways, adults, including television role models, pass on their ideas about "appropriate" behaviors for boys and girls (Else-Quest et al., 2010; Parke & Buriel, 2006; Ruble, Martin, & Berenbaum, 2006). They also convey information about gender-appropriate interests. For example, sixth-grade girls and boys express equal interest in science and earn the same grades. However, parents tend to underestimate their daughters' interest, believe that science is difficult for them, and are less likely to give them scientific explanations when working on a physics task (Tenenbaum & Leaper, 2003).

Children also pick up notions of what is gender-appropriate behavior from their peers. By the time they are in preschool, boys and girls are more likely to play with children of the same sex (Martin & Ruble, 2009). These same-sex peers model and enforce gender role standards and provide the strongest influence on children's gender-typed behavior (Leaper & Friedman, 2007; Rose & Rudolph, 2006).

Cognitive Factors in Gender Roles Because most children want to be accepted, especially by their peers, they become "gender detectives," searching for clues about who should do what, who can play with whom, and in what ways girls and boys are different (Martin & Ruble, 2004). In the process, they develop **gender schemas**, which are generalizations about the toys and activities that are "appropriate" for boys and for girls and the jobs that are "meant" for men or for women (Fagot, 1995). Once they have developed these gender schemas and know that they themselves are male or female, children tend to choose the activities, toys, and behaviors deemed appropriate for their own gender (Ruble, Martin, & Berenbaum, 2006; Zosuls et al., 2009). They

gender schemas The generalizations children develop about what toys, activities, and occupations are "appropriate" for males and for females.

become "sexist self-socializers" as they work at developing the masculine or feminine attributes they view as consistent with their self-image as a male or a female. By the age of 8 or 9, they may have become a little more flexible about what's acceptable for members of each sex to do—but most still say they wouldn't be friends with a boy who wore lipstick or a girl who played football (Levy, Taylor, & Gelman, 1995). Later in elementary school, when most girls outperform boys in language arts, math, science, and social studies, girls think of themselves as good only in language arts, because that's what they are "supposed" to be good at (Pomerantz, Altermatt, & Saxon, 2002).

In summary, social training by both adults and peers, along with the child's own cognitions about the world, tends to bolster and amplify any biological predispositions that distinguish boys and girls. This process in turn creates gender roles that are the joint and inextricably linked products of nature and nurture. This and other elements of early development are summarized in "In Review: Social and Emotional Development During Infancy and Childhood."

The efforts of some parents to deemphasize gender roles in their children's upbringing may help reduce the magnitude of gender differences in areas such as verbal and quantitative skills, occupational ambitions, and preferences for particular toys. However, the evolutionary approach to psychology suggests that other gender differences—such as males' greater ability to visualize the rotation of objects in space and females' greater ability to read facial expressions—are unlikely to change much (Quinn & Liben, 2008). Evolutionary psychologists see these differences as deeply rooted in the distant past, when males' major activity was hunting and females' was child rearing (Buss, 2004a). Other psychologists have suggested that prenatal exposure to male or female hormones influences the organization of male and female brains in different ways (Halpern, 1997; Vuoksimaa et al., 2010). Still others see such differences as reflecting social inequality, not just biological destiny (Wood & Eagly, 2002). Whatever the source of gender differences, it is important to remember that most of them are quite small (Hyde, 2005). So even though a popular book suggests that "men are from Mars and women are from Venus," a more accurate metaphor might be to say that men are from one state and women are from another (Hyde, 2005).

IN REVIEW Social and Emotional Development During Infancy and Childhood

Age	Relationships with Parents	Relationships with Other Children	Social Understanding
Birth–2 years	Infants form an attachment to the primary caregiver.	Play focuses on toys, not on other children.	Infants respond to emotional expressions of others.
2–4 years	Children become more autonomous and no longer need their parents' constant attention.	Toys are a way of eliciting responses from other children.	Young children can recognize emotions of others.
4–10 years	Parents actively socialize their children.	Children begin to cooperate, compete, play games, and form friendships with peers.	Children learn social rules, such as politeness, and roles, such as being male or female; they learn to control their emotions.

1. As part of their social development, children learn ____________, which tell them what patterns of appearance and behavior are associated with being male or female.

2. Teaching children to talk quietly in a restaurant is part of the process called ____________.

3. Strict rules and the threat of punishment are typical of ____________ parting.

Risk and Resilience

Family instability, child abuse, homelessness, parental unemployment, poverty, substance abuse, and domestic violence put many children at risk for various difficulties in social and emotional development (Ackerman, Brown, & Izard, 2004; Karevold et al., 2009). When parents divorce, for example, their children may develop serious problems (Clarke-Stewart & Brentano, 2006; Lansford, 2009). By two or three years after the divorce, the intense psychological stress is over, and most children are functioning competently, but there can be long-lasting effects. Adults whose parents had divorced when they were children may not live as long as those from intact families, and a high proportion of people who were young adolescents when their parents divorced are unable to form committed relationships even years later. Children are also at risk if their parents have violent fights. Nearly half the children exposed to marital violence exhibit various forms of psychological disorder—a rate six times higher than that in the general population (Garber, 1992).

Children vary in how well they ultimately adjust to all these stressors. Even when the odds are against them, some children are left virtually unscathed by even the most dangerous risk factors. These children are said to be resilient. **Resilience** is a characteristic that permits successful development in the face of significant challenge. It has been studied throughout the world in a variety of adverse situations, including war, natural disaster, family violence, child maltreatment, and poverty. This research has consistently identified certain qualities in children and their environments that are associated with resilience. Specifically, resilient children tend to be intelligent and to have easy temperaments, high self-esteem, talent, and faith (Masten & Coatsworth, 1998). They are cheerful, focused, and persistent in completing a task (Wills et al., 2001). They also typically have significant relationships with a warm and authoritative parent, with someone in their extended family, or with other caring adults outside the family, at school, or in clubs or religious organizations (Rutter, 2006). In addition, they have genes that direct optimal regulation of serotonin, a neurotransmitter that, as described in the chapter on biological aspects of psychology, plays a role in mood and stress-related responses (Kim-Cohen & Gold, 2009).

Adolescence

The years of middle childhood usually pass smoothly, but adolescence changes things drastically. All adolescents undergo significant changes in size, shape, and physical capacities. Many also experience big changes in their social lives, reasoning abilities, and views of themselves.

Changes in Body, Brain, and Thinking

A sudden spurt in physical growth is the most visible sign that adolescence has begun. This growth spurt peaks at about age 12 for girls and age 14 for boys (Tanner, 1978; see Figure 12.6). Suddenly, adolescents find themselves in new bodies. At the end of the growth spurt, females begin to menstruate, and males produce live sperm. This state of being able for the first time to reproduce is called **puberty**.

These dramatic changes in teenagers' bodies are accompanied by significant changes in their brains, especially in parts of the frontal lobes known as the prefrontal cortex (Kuhn, 2006; Spear, 2000; see Figure 3.15 in the chapter on biological aspects of psychology). These areas are vital to the ability to think flexibly, to act appropriately in challenging situations, and to juggle multiple pieces of information. They are also involved in skills such as planning and organization, controlling impulses, and allocating attention.

As described in the Linkages section of the chapter on biological aspects of psychology, the brain overproduces neuronal connections during childhood, but during

resilience A quality allowing children to develop normally in spite of severe environmental risk factors.

puberty The condition of being able, for the first time, to reproduce.

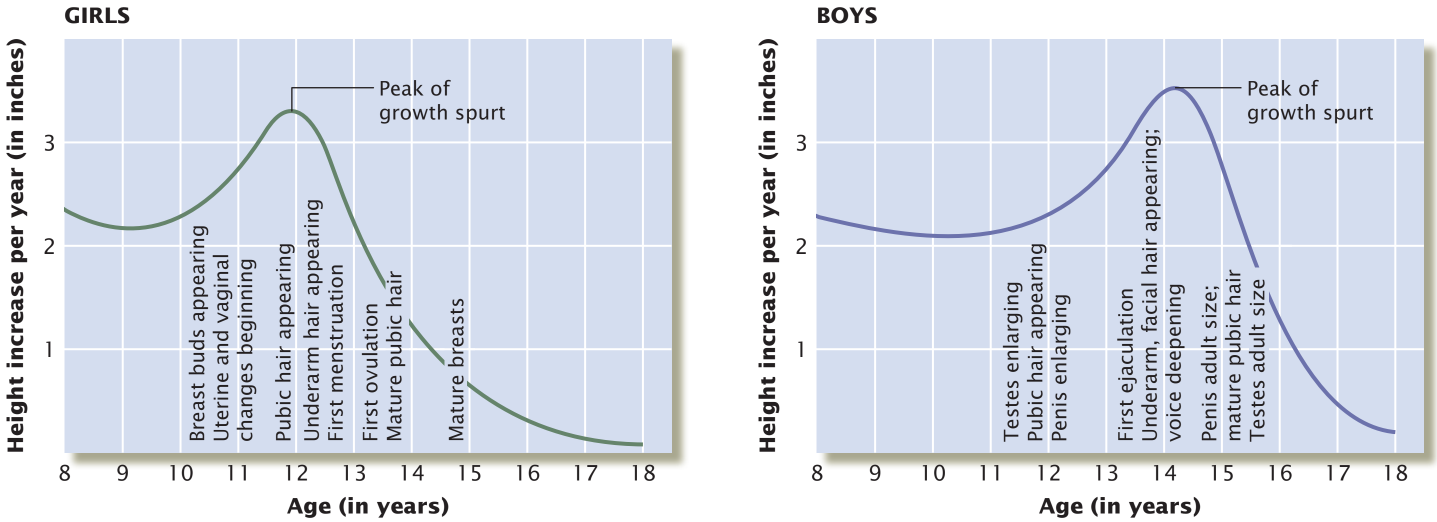

FIGURE 12.6

Physical Changes in Adolescence

At about 10½ years of age, girls begin their growth spurt, and by age 12, they are taller than their male peers. Boys begin their growth spurt at about 12½ years of age and usually grow faster and for a longer period of time than girls. Adolescents may grow in height as much as 5 inches a year. Increases in sex hormones (e.g., estrogen and testosterone) lead to the development of sexual characteristics such as pubic hair. The ages at which these changes occur vary considerably across individuals, but their sequence is the same.

puberty, the connections that are not being used much are eliminated, or "pruned." At the same time, many neurons acquire a sheath of myelin, which speeds their communication with one another. So by the end of adolescence, teenagers' brains have fewer neural connections, but those that remain are more selective, stronger, and more efficient. At the same time, dopamine, a neurotransmitter associated with the experience of pleasure, becomes more prominent.

Changes in the brain are reflected in changes in the ways that adolescents think. As mentioned earlier, Piaget described this new stage of thinking as the *formal operational stage.* He said it is marked by the ability to engage in abstract, hypothetical thinking, but researchers now suggest that cognitive changes in adolescence also include a whole range of executive functions controlled by the prefrontal cortex (Keil, 2006; Kuhn, 2006). By late adolescence, young people are able to reason better, plan for the future, and foresee consequences. When they investigate a topic, they are able to consider and control several factors at once and analyze the impact of what they discover. This ability to engage in strategic, self-organized thinking also allows them to perform more than one mental task at the same time (Luciana et al., 2005). Moreover, they increasingly take charge of their mental life, choosing what to think about, when and where to do so, and how to allocate their mental effort.

Adolescent Feelings and Behavior

In Western cultures, the changes occurring during *early adolescence,* from ages 11 to 14 or so, can be disorienting. Adolescents—especially early-maturing girls—may experience bouts of depression, insomnia, and other psychological problems (Johnson et al., 2006; Mendle, Turkheimer, & Emery, 2007; Ohring, Graber, & Brooks-Gunn, 2002). This is also the time when eating disorders are likely to first appear (Wilson et al., 1996) and when the incidence of attempted and completed suicides begins to rise (Centers for Disease Control and Prevention, 2007).

As sex hormones and pleasure-related brain systems become more active, sexual interest stirs, and the prospect of smoking, drinking alcohol, and taking other drugs becomes more appealing (Patton et al., 2004; Reyna & Farley, 2006). Opportunities to do these things increase too because adolescents spend more time with their peers and take more risks than younger children do (Gardner & Steinberg, 2005; Steinberg, 2007, 2008). Much of this risk-taking seems to be due to the different rates at which parts of the adolescent brain develop. The impulse control areas in the prefrontal cortex complete their development long after the emotional and reward-related areas of the limbic system do (Casey, Getz, & Galvan, 2008; Steinberg, 2007, 2008). Of course, a certain amount of adolescent risk-taking and sensation-seeking is normal. In fact,

Contacting Friends—Instantly

Adolescents spend more time online and more often use instant messaging (texting) and other electronic communication technologies than either adults or children. Most often they use the Internet to communicate with their existing network of friends and find that this enhances both their friendships and their sense of well-being (Valkenburg & Peter, 2007a, 2007b). About a third believe that online communication is more effective than in-person chat for disclosing intimate personal information. Some early studies created concern that intense Internet use might have negative long-term effects on adolescent texters' ability to plan, think flexibly and abstractly, learn rules, inhibit inappropriate actions, and focus on relevant information. More recent research suggests that these concerns may be exaggerated (Valkenburg & Peter, 2009). There is no doubt, though, that the Internet carries risks, including exposure to degrading or obscene material and attempted contact by sexual predators.

adolescents who engage in moderate risk-taking tend to be more socially competent than those who either take no risks or take extreme risks (Spear, 2000). Extreme risk-taking is often maladaptive, leading to excessive use of drugs and alcohol or to reckless and even life-threatening activities. So for some people, early adolescence marks the beginning of a downward spiral that ends up in academic failure, delinquency, and substance abuse.

Many of the problems of adolescence are associated with challenges to young people's *self-esteem*, their sense of being worthy, capable, and deserving of respect (Harter, 2006). Adolescents are especially vulnerable if many stressors occur at the same time (Kling et al., 1999). The switch from elementary school to middle school or junior high is particularly challenging (Eccles, Lord, & Buchanan, 1996). The new teachers may have less time to nurture students and may exert more control, impose higher standards, and evaluate students' work in a more public way. Under these circumstances, grades may drop, especially for students who were already having trouble in school or who don't have confidence in their own abilities (Rudolph et al., 2001). But grades don't affect self-esteem in all teens. Some base their self-esteem more on athletic success and on their peers' opinions of them than on their academic achievement (Crocker & Wolfe, 2001). In fact, adolescents' academic performance is strongly affected by the peers with whom they spend their time. For example, adolescents whose grades and motivation decline from the end of elementary school to the end of their first year in middle school tend to be those who affiliated themselves with other academic underachievers (Ryan, 2001).

The changes and pressures of adolescence are often played out at home as adolescents try to have a greater say in a parent-child relationship once ruled by the parents. Serious conflicts may lead adolescents—especially those who do not feel close to their parents—to serious problems, including running away, getting pregnant, stealing, taking drugs, or even attempting suicide (Blum, Beuhring, & Rinehart, 2000; Goldstein, Davis-Kean, & Eccles, 2005). Fortunately, although the bond with parents deteriorates during the transition from early to mid adolescence, most adolescents maintain a reasonably good relationship with their parents (McGue et al., 2005; Moore, 2005; van Wel, ter Bogt, & Raaijmakers, 2002). Children who report positive relationships with their parents tend not to associate with risk-taking peers in middle school or develop problem behaviors in high school (Eisenberg et al., 2005; Goldstein, Davis-Kean, & Eccles, 2005; Soenens et al., 2006).

Teens are most likely to share confidences with parents who keep tabs on their youngsters' activities and expect them to discuss those activities (Smetana et al., 2006; Soenens et al., 2006), but how much involvement and control is enough and how much is too much? It is not easy for parents to know. In one study, seventh-graders who felt they had a lot of autonomy at home—such as deciding how late to stay out at night—did more unsupervised socializing with peers in eighth grade and were at greater risk for problem behavior in eleventh grade (Goldstein, Davis-Kean, & Eccles, 2005). At the same time, seventh-graders who thought their parents were too intrusive also ran into problems. They hung out more with deviant peers in eighth grade and by eleventh grade showed elevated rates of behavior problems.

Love and Sex in Adolescence On top of everything else, adolescence is usually the time when romance first takes center stage (Collins & Steinberg, 2006). Nearly half of 15-year-olds and 70 percent of 18-year-olds in the United States have romantic relationships; 60 percent of these relationships last a year or more (Carver, Joyner, & Udry, 2003). Being in a romantic relationship is linked with feelings of self-worth, competence, and belonging to a peer group (Collins & Roisman, 2006; Harter, 2006). Dating a popular, socially skilled partner is even better because this can increase a previously isolated or poorly adjusted teen's popularity while reducing victimization and feelings of sadness (Simon, Aikins, & Prinstein, 2008).

Surveys suggest that almost half of teens in the United States have had sexual intercourse by age 16 (Kaiser Family Foundation, 2005). Teens who have sex differ from those who do not in a number of ways. They hold less conventional attitudes and values, and they are more likely to smoke, drink alcohol, and use other drugs (National Center on Addiction and Substance Abuse, 2004), to be aggressive, and to have attention problems in school (Schofield et al., 2008). They are also likely to have more unsupervised time after school (Cohen et al., 2002), to be in peer groups whose norms support risk-taking (diNoia & Schinke, 2008), and to have a sexually active best friend (Jaccard, Blanton, & Dodge, 2005). Their parents tend to be less educated, to have less control over them, and not to talk openly with them. They are more likely to have spent their childhood without their father (Ellis et al., 2003; Mendle et al., 2009). The typical pairing of heterosexually active teens is a “macho” male and a “girly” female (Udry & Chantala, 2003). Adolescents who displayed poorer self-regulatory skills as children are the ones most likely to take greater sexual risks, such as having multiple partners or not using condoms (Atkins, 2008; Raffaelli & Crockett, 2003).

All too often, sexual activity leads to declining school achievement, sexually transmitted diseases, and unplanned and unwanted pregnancies. Teenage girls have higher rates of gonorrhea, chlamydia, pelvic inflammatory disease, and other sexually transmitted diseases than any other age group in the United States (Forhan et al., 2009; Malhotra, 2008; Ross, 2002). Nearly 18 percent of them become pregnant (Perper & Manlove, 2009). Although the rates of teen pregnancy and birth in the United States declined between 1991 and 2005, they are once again on the rise (Moore, 2009). The teens most likely to become pregnant are those with low confidence in themselves and their educational futures, along with those whose parents are unmarried and have a low level of education (Chandra et al., 2008; Young et al., 2004).

Giving birth in adolescence can create problems for the mother, the baby, and others in the family. For one thing, the younger sisters of teenage mothers may have to take time away from schoolwork to help care for the child, and they are at increased risk for drug and alcohol use and for becoming pregnant themselves (East & Jacobson, 2001). Worse still is the fact that the babies of teenage mothers are less likely than babies of older mothers to survive their first year (Phipps, Blume, & DeMonner, 2002). This situation occurs partly because compared with older parents, teenage parents are less positive and stimulating with their children and more likely to abuse them (Brooks-Gunn & Chase-Lansdale, 2002). The children of teenage parents are more likely to develop behavior problems and to do poorly in school than children with more

Mothers Too Soon?

More than half of the U.S. adolescents who become pregnant elect to keep their babies and become single mothers. These young women and their children are likely to face special academic, social, and other problems. Accordingly, support programs for teenage mothers have been developed, and some of them have reported success in alleviating symptoms of depression, increasing the young mothers’ parenting capabilities, and helping them achieve their educational goals (Cox et al., 2008; Sadler et al., 2007).

mature parents (Furstenberg, Brooks-Gunn, & Chase-Lansdale, 1989; Moffitt, 2002). They do better if they have a strong attachment to their father and if their mother was prepared for maternal responsibilities and was knowledgeable about children and parenting before the baby was born (Miller et al., 1996; Whitman et al., 2001).

Violent Adolescents As described at the beginning of this chapter, some individuals respond to the challenges of adolescence with violence. The roots of teenage violence run deep and lie partly in genetic factors (Brendgen et al., 2005). From childhood to adolescence, aggression is just as stable as intelligence (Dodge, Coie, & Lynam, 2006). Among the childhood characteristics that increase the risk of violent behavior in adolescence are fearlessness, low intelligence, lack of empathy, lack of emotional self-regulation, aggressiveness, and moral disengagement (Eisenberg et al., 2004; Hay et al., 2003; Pepler et al., 2008; Rutter, 2003). Gender is another important factor (Ostrov & Godleski, 2010): It is no coincidence that teenage killers are almost always boys. In cultures around the world, homicides committed by males outnumber those committed by females by more than thirty to one (Cassel & Bernstein, 2007).

Several environmental factors are also associated with an increased risk of youth violence (Duke et al., 2010). These factors include maternal depression and rejection and involvement with delinquent gangs or antisocial peers (Burt, McGue, & Iacono, 2009; Rutter, 2003), as well as poverty (Strohschein, 2005), malnutrition (Liu et al., 2004), and exposure to violent television and video games (Comstock & Scharrer, 2006; Nicoll & Kieffer, 2005). Peers are especially influential. In one study, adolescents were more likely to say they would engage in aggressive behaviors if they believed they were in a chat room with popular adolescents who favored aggressive behaviors (Cohen & Prinstein, 2006). Another contributor to violence is the growing use and abuse of anabolic steroids (Grimes, Ricci, & Melloni, 2006). Adolescent violence is also more likely among youngsters who grow up witnessing family violence, clashing with siblings, or experiencing physical abuse (Ehrensaft et al., 2003; Noland et al., 2004). The risk is raised, too, among children who live in neighborhoods plagued by violence and crime (Herrenkohl et al., 2004; Pearce et al., 2003). Young people who are exposed to even a single incident of firearm violence are twice as likely as other children to later engage in violent behavior (Bingenheimer, Brennan, & Earls, 2005).

The cascade of environmental conditions leading to violent behavior in adolescence was described in a study of children as they grew from ages 5 through 18 (Dodge et al., 2008). These children spent their early years in a socially and economically disadvantaged family situation where harsh, inconsistent parenting impaired the children's social and cognitive development. This impaired development made these children prone to learning and conduct problems that led to social and academic failure in elementary school. As their increasingly unmanageable behavior caused their parents to stop supervising and monitoring them, these children were more likely to associate with antisocial peers (sometimes including gangs). The final result, in adolescence, was that these youngsters became more likely to carry a weapon, to threaten others with that weapon, to be involved in gang fights, and to attack anyone whom they perceive as a threat to their safety.

Despite all the potential dangers and problems of adolescence, most teens in Western cultures are not violent and do not experience major personal turmoil or family conflicts. So although most parents and teachers seem to believe that adolescence is a time of "storm and stress" (Hines & Paulson, 2007), research suggests that more than half of today's teens find adolescence relatively trouble-free (Arnett, 1999, 2007b; Chung, Flook, & Fuligni, 2009). Only about 15 percent of the adolescents studied experience serious distress (Steinberg, 1990). The vast majority of adolescents cope well with the changes puberty brings and soon find themselves in the midst of perhaps the biggest challenge of their young lives: preparing themselves for the transition to young adulthood.

Identity and Development of the Self

In many less developed countries today, as in the United States in the nineteenth century, the end of early adolescence, around the age of 15, marks the beginning of adulthood: of work, parenting, and grown-up responsibilities. In modern North America, though, the transition from childhood to adulthood often lasts well into the twenties. This lengthened adolescence has created special problems, including the matter of finding or forming an identity.

Most adolescents have not previously thought deeply about who they are. At the age of 3 or 4, if asked to describe themselves, they would probably have mentioned their physical features ("I have blue eyes"), preferences ("I like pizza"), and possessions ("I have a kitty"). At ages 5 to 7, they would have described their competencies ("I'm a good runner, and I get good grades at school"). Around the age of 8, they would have used labels that focus on more complex and general abilities ("I'm smart") and interpersonal attributes ("I'm popular") and would have used this knowledge about themselves to actively evaluate and reflect on their thoughts and behavior (Davis-Kean, Jager, & Collins, 2009). It is in early adolescence, around age 11, that they would have begun to describe themselves in terms of social relationships, personality traits, and other general, stable psychological characteristics; by the end of adolescence, their self-descriptions emphasize their personal beliefs, values, and moral standards (Harter, 1999, 2006). Adolescents come to recognize that they are somewhat different people in different social contexts (such as with friends versus at a family party), and they can think about the possible selves they might be in the future. They can also integrate their seemingly opposite traits, such as "cheerful" and "depressed," into a broader characteristic, such as "moody."

These changes in the way adolescents describe themselves suggest changes in the way they think about themselves too. As they become more self-conscious, they gradually develop a personal identity as unique individuals. That personal identity may be affected by their **ethnic identity**—the part of a person's identity that reflects the racial, religious, or cultural group to which the person belongs (Quintana, 2010). Adolescents who achieve a clear, positive ethnic identity exhibit higher self-esteem, greater optimism, and more social competence, as well as more positive feelings toward their own ethnic group (Chavous et al., 2003; Spencer, 2006; Wong, Eccles, & Sameroff, 2003; Yip & Fuligni, 2002). This pattern is seen especially among adolescents who do not experience much ethnic discrimination (Greene, Way, & Pahl, 2006). Adolescents with a strong ethnic identity are also more positive about education, more likely to

Ethnic Identity

TRY THIS Ethnic identity is that part of our personal identity that reflects the racial, religious, or cultural group to which we belong. Ethnic identity often leads people to interact mainly with others who share that identity. To what extent is this true of you? You can get a rough idea by jotting down the ethnicity of all the people you chose to spend time with over the past week or so.

ethnic identity The part of a person's identity associated with the racial, religious, or cultural group to which the person belongs.

do better academically, and less likely to become delinquents (Adelabu, 2008; Bruce & Waelde, 2008; Fuligni, Witkow, & Garcia, 2005).

As described in the chapter on social cognition, the same processes that create a strong ethnic identity can also sow the seeds of ethnic prejudice. For example, thinking favorably about your own ethnic group can lead to thinking of other groups as inferior. Fortunately, prejudice is not inevitable. Adolescents who regularly interact with members of other ethnic groups usually develop more mature ethnic identities and express more favorable attitudes toward people of other ethnicities (Phinney, Ferguson, & Tate, 1997; Phinney, Jacoby, & Silva, 2007).

Moral Development

Adolescents are able to develop a personal and ethnic identity partly because, according to Piaget's theory, they have entered the formal operational stage, which allows them to think logically and reason about abstract concepts. Adolescents often find themselves applying these advanced cognitive skills to questions of morality.

Kohlberg's Stages of Moral Reasoning To examine how people think about morality, Lawrence Kohlberg asked them to resolve moral dilemmas. Perhaps the most famous of his dilemmas was the "Heinz dilemma," which requires people to decide whether a man named Heinz should steal a rare and unaffordable drug in order to save his wife's life. Kohlberg found that the reasons people give for their moral choices change systematically with age (Kohlberg & Gilligan, 1971). He proposed that moral reasoning develops in six stages, which are summarized in Table 12.3. These stages are not tightly linked to a person's age. There is a range of ages for reaching each stage, and not everyone reaches the highest level.

Stage 1 and Stage 2 moral judgments are most typical of children under the age of 9 and tend to be selfish. Kohlberg called this level **preconventional reasoning** because it is not yet based on the conventions or rules that guide social interactions in society. At this level of **moral development**, people are concerned with avoiding punishment or following rules when it is to their own advantage. At the **conventional reasoning** level, Stages 3 and 4, people are concerned about other people; they believe that morality consists of following rules and conventions such as duty to the family, to marriage vows, and to the country. Conventional thinkers would never think it was proper to burn their country's flag in protest, for example. The moral reasoning of children and adolescents from ages 9 to 19 is most often at this level. Stages 5 and 6 represent what Kohlberg called **postconventional reasoning** because it occurs after conventional reasoning. Moral judgments at this level are based on personal standards or universal principles of justice, equality, and respect for human life rather than on the demands of authority figures or society. People whose moral reasoning is at this level view rules and laws as arbitrary but respect them because they protect human welfare. They believe that individual rights can sometimes justify violating these laws if the laws become destructive. People do not usually reach this level until sometime in young adulthood—if at all. Stage 6 is seen only rarely in extraordinary individuals.

Limitations of Kohlberg's Stages Studies of Kohlberg's stages have generally supported the sequence he proposed (e.g., Turiel, 2006). Evidence for Kohlberg's first four stages has been found in twenty-seven cultures from Alaska to Zambia. Stages 5 and 6, however, have not always appeared (Gibbs et al., 2007; Snarey & Hooker, 2006; Turiel, 2006; Wainryb, 2006). Further, moral judgments made in some cultures do not always fit neatly into Kohlberg's stages. Some people in collectivist cultures—Papua New Guinea, Taiwan, and Israeli kibbutzim, for example—explained their answers to moral dilemmas by pointing to the importance of the community rather than to personal standards. People in India included in their moral reasoning the importance of acting in accordance with one's gender and caste and with maintaining personal purity. As in other areas of cognitive development, culture plays a significant role in shaping moral judgments.

Gender may also play a role. Carol Gilligan (1982, 1993) suggested that for females, the moral ideal is not the abstract, impersonal concept of justice that Kohlberg found

preconventional reasoning Moral reasoning that is not yet based on the conventions or rules that guide social interactions in society.

moral development The growth of an individual's understanding of the concepts of right and wrong.

conventional reasoning Moral reasoning that reflects the belief that morality consists of following rules and conventions.

postconventional reasoning Moral reasoning in which judgments are based on personal standards or universal principles of justice, equality, and respect for human life.

TABLE 12.3 Kohlberg's Stages of Moral Development

Kohlberg's stages of moral reasoning describe differences in how people think about moral issues. Here are examples of the answers that people at different stages of development might give to the "Heinz dilemma" described in the text. This dilemma is more realistic than you might think. In 1994, a man was arrested for robbing a bank after being turned down for a loan to pay for his wife's cancer treatments; a similar case occurred in 2004.

Stage	What Is Right?	Should Heinz Steal the Drug?
Preconventional		
1	Obeying, and avoiding punishment from, a superior authority	"Heinz should not steal the drug because he will be jailed."
2	Making a fair exchange, a good deal	"Heinz should steal the drug because his wife will repay him later."
Conventional		
3	Pleasing others and getting their approval	"Heinz should steal the drug because he loves his wife and because she and the rest of the family will approve."
4	Doing your duty, following rules and social order	"Heinz should steal the drug for his wife because he has a duty to care for her" or "He should not steal the drug because stealing is illegal."
Postconventional		
5	Respecting rules and laws but recognizing that they may have limits	"Heinz should steal the drug because life is more important than property."
6	Following universal ethical principles, such as justice, reciprocity, equality, and respect for human life and rights	"Heinz should steal the drug because of the principle of preserving and respecting life."

in males but rather the need to protect enduring relationships and fulfill human needs. When Gilligan asked her research participants about moral conflicts, the majority of men focused on justice, but only half of the women did. The other half focused on caring. Although this difference between men and women has not always been found, there does seem to be a tendency for females to focus on caring more than males do and for males to focus on justice more than females do when they are talking about real-life moral issues they have personally experienced (Jaffe & Hyde, 2000). However, when they are asked about hypothetical moral dilemmas, there is no substantial difference in how males and females reason (Jaffe & Hyde, 2000; Raaijmakers, Engels, & Van Hoof, 2005; Walker, 2006).

Taken together, the results of research in many countries and with both genders suggest that moral ideals are not absolute and universal. Moral development is an adaptation to the world in which one lives, a world that differs from place to place and time to time (Turiel, 2006; Wainryb & Psaupathi, 2008).

Moral Reasoning and Moral Action Moral reasoning is related to moral behavior. In one study, adolescents who committed crimes ranging from burglary to murder tended to see obedience to laws mainly as a way of avoiding jail—a Stage 1 belief. Their nondelinquent peers, who showed Stage 4 reasoning, believed that one should obey laws because they prevent chaos in society (Gregg, Gibbs, & Basinger, 1994). But having advanced moral reasoning ability is no guarantee that a person will always act morally; other factors, such as the likelihood of being caught in an immoral act, also affect behavior. For example, people have been shown to behave in less moral ways when dim lighting or the use of e-mail creates a sense of anonymity or distance (Naquin, Kurtzberg, & Belkin, 2010; Zhong, Bohns, & Gino, 2010) and to behave more honestly when they feel they are being watched. In one study, even people alone in a coffee lounge were nearly three times as likely to pay for their coffee when a poster on the wall portrayed human eyes looking at them rather than an image of flowers (Bateson, Nettle, & Roberts, 2006).

In summary, learning to behave in moral ways requires three things: (1) consistent modeling of moral reasoning and behavior by parents and peers, (2) real-life experience with moral issues, and (3) situational factors that support moral actions (Aquino et al., 2009).

Emerging Adulthood

In Western cultures, adolescence is typically followed by a period of "emerging adulthood" that lasts from about 18 to about 25. During this period, young people explore life's possibilities through education, dating, and travel before settling into stable adult roles and responsibilities (Arnett, 2000, 2007a; Roisman et al., 2004). One of the tasks of particular importance for emerging adults is resolving their "identity crisis."

Facing the Identity Crisis According to Erikson (1968), events of late adolescence, such as graduating from high school, going to college, and building new relationships, challenge one's self-concept and precipitate an **identity crisis** (see Table 12.2). In this crisis, the person must develop an integrated self-image as a unique individual by pulling together self-knowledge acquired during childhood. If infancy and childhood brought trust, autonomy, and initiative, according to Erikson, individuals will resolve the identity crisis positively, feeling self-confident and competent. If infancy and childhood resulted in feelings of mistrust, shame, guilt, and inferiority, individuals will be confused about their identity and goals.

In Western cultures, there is some limited empirical support for Erikson's ideas about the identity crisis. In the period of emerging adulthood, young people do become more open to new experiences and consider alternative identities (Roberts, Walton, & Viechtbauer, 2006). They "try out" being rebellious, studious, or detached as they attempt to resolve questions about sexuality, self-worth, industriousness, and independence. Some college students, for example, make a commitment to an identity and then reevaluate that commitment; these students are more likely to repeat their freshman year or change their major (Luyckx, Goossens, & Soenens, 2006). Recreational identities may be especially important; not all college students are successful academically, so they may try out alternative identities associated with extracurricular activities (Eccles & Gootman, 2002). People of college age may also try out identities through online message boards and multiplayer Internet games (Whitlock, Powers, & Eckenrode, 2006).

As young people learn to cope with challenges, handle their emotions, and settle on their identity during emerging adulthood, their psychological well-being tends to improve. The prevalence of serious depression, which tends to be quite high at the end of adolescence, especially for girls, declines (Galambos, Barker, & Krahn, 2006). By the time they are 21, about half of the people studied have resolved the identity crisis in a way that is consistent with their self-image and the historical era in which they are living. They are ready to enter adulthood with greater self-confidence, more mature attitudes and behavior, more consistent goals and values, and a clearer idea of who they are (Savin-Williams & Demo, 1984). Many have become more aware of their obligations to their families (Fuligni & Pedersen, 2002). Those who explore matters of identity more extensively tend to have had opportunities to express and develop their own points of view in a supportive environment at home, at school, and in the community (Dumas et al., 2009; Grotevant, 1998). For those who fail to resolve identity issues—either because they avoided an identity crisis by accepting whatever identity their parents set for them or because they postponed dealing with the crisis and remain uncommitted and lacking in direction—problems often lie ahead (Lange & Byrd, 2002).

identity crisis A phase during which an adolescent attempts to develop an integrated self-image.

Adulthood

As emerging adults enter adulthood itself, the process of development continues. The changes and transitions in adulthood can be divided roughly into three periods: early adulthood (from 20 to about 39), middle adulthood (from 40 to 65), and late adulthood (beyond 65).

Physical Changes

In *early adulthood,* physical growth continues. Shoulder width, height, and chest size increase. People continue to develop their athletic abilities. For most people, the years of early adulthood are the prime of life.

In *middle adulthood,* one of the most common physical changes is the loss of sensory sharpness. By this time, nearly everyone shows some hearing impairment. People in their early forties become less sensitive to light, and their vision deteriorates somewhat. Increased farsightedness is an inevitable change that usually results in a need for reading glasses. Inside the body, bone mass is dwindling, the risk of heart disease is increasing, and fertility declines. In their late forties or early fifties, women generally experience the shutdown of reproductive capability, a process known as **menopause.** Estrogen and progesterone levels drop, and the menstrual cycle eventually ceases.

In *late adulthood,* men shrink about an inch and women about 2 inches as their posture changes and cartilage disks between the spinal vertebrae become thinner. Hardening of the arteries and a buildup of fat deposits on the artery walls may lead to heart disease. The digestive system slows down and becomes less efficient. In addition, the brain shrinks, and the flow of blood to the brain slows. The few reflexes that remained after infancy (such as the knee-jerk reflex) weaken or disappear. Bedtime comes earlier, and naps are more frequent (Park et al., 2002). But as in earlier years, declines in physical functioning can be delayed or diminished by a healthy diet and exercise (Brach et al., 2003; Larson et al., 2006; Sun et al., 2010).

Cognitive Changes

Adulthood is marked by both increases and decreases in cognitive abilities. Reaction times become slower and more variable (Deary & Der, 2005), and abilities that involve intensive information processing begin to decline, even in early adulthood. However, abilities that depend on accumulated knowledge and experience increase and don't begin to decline until old age, if at all. In fact, older adults may function as well as or even better than younger adults in situations that tap their long-term memories and well-learned skills (Campbell, Hasher, & Thomas, 2010).

Cognitive Advances in Early, Middle, and Late Adulthood In early and middle adulthood, until age 60 at least, important cognitive abilities improve. During this period, adults do better on tests of vocabulary, comprehension, and general knowledge, especially if they use these abilities in their daily lives (Park, 2001). Young and middle-aged adults learn new information and new skills; they remember old information and hone old skills. It is in their forties through their early sixties that people tend to put in the best performance of their lives on complex mental tasks such as reasoning, verbal memory, and vocabulary (Willis & Schaie, 1999).

The nature of thought may also change during adulthood. Adult thought is often more complex and adaptive than adolescent thought (Labouvie-Vief, 1992). Adults can understand, as adolescents cannot, the contradictions inherent in thinking. They see both the possibilities and the problems in every course of action—in deciding whether to start a new business, back a political candidate, move to a new community, or change jobs, for example. Middle-aged adults are more adept than adolescents or young adults at making rational decisions and at relating logic and abstractions to

menopause The process whereby a woman's reproductive capacity ceases.

actions, emotions, social issues, and personal relationships (Tversky & Kahneman, 1981). Their thought becomes more global, more concerned with broad moral and practical concerns (Labouvie-Vief, 1982). It has been suggested that this new kind of thinking reflects a stage of cognitive development that goes beyond Piaget's formal operational period. In this advanced stage, people's thinking becomes *dialectical*, which means they understand that knowledge is relative, not absolute—such that what is seen as wise today may have been thought foolish in times past (Lutz & Sternberg, 1999). They see life's contradictions as an inevitable part of reality, and they tend to weigh various solutions to problems rather than just accepting the first one that springs to mind (Grossmann et al., 2010).

Declining Cognitive Abilities in Late Adulthood It is not until late adulthood—after age 65 or so—that some intellectual abilities decline noticeably (Craik & Salthouse, 2008). Generally, the abilities most severely affected are those that require rapid and flexible manipulation of ideas and symbols, active thinking and reasoning, and sheer mental effort (Baltes, 1994; Finkel et al., 2003; Gilmore, Spinks, & Thomas, 2006; see Figure 12.7). Older adults do just as well as younger ones at tasks they know well, such as naming familiar objects (Radvansky, 1999). It is when they are asked to perform an unfamiliar task or to solve a complex problem they have not seen before that older adults are generally slower and less effective than younger ones (Craik & Rabinowitz, 1984). When facing complex problems, older people apparently suffer from having too much information to sift through (Gazzaley et al., 2005). They have trouble considering, choosing, and executing solutions (Peters et al., 2007). As people age, they grow less efficient at organizing the elements of a problem and at holding and manipulating more than one idea at a time. They have difficulty doing tasks that require them to divide their attention between two activities (Smith et al., 2001) and are slower at shifting their attention back and forth between those activities (Wecker et al., 2005). If older adults have enough time, though, and can separate the two activities, they can perform just as well as younger adults (Hawkins, Kramer, & Capaldi, 1993).

Usually, the loss of intellectual abilities in older adults is slow and need not cause major problems (Bashore & Ridderinkhoff, 2002). A study of Swedish adults (Nilsson, 1996) found that memory problems among older adults appear mainly when retrieving events from *episodic memory* (such as what they ate for lunch yesterday) rather than in retrieving general knowledge from *semantic memory* (such as the name of the capital of Spain). In short, everyday competencies that involve verbal processes are likely to remain

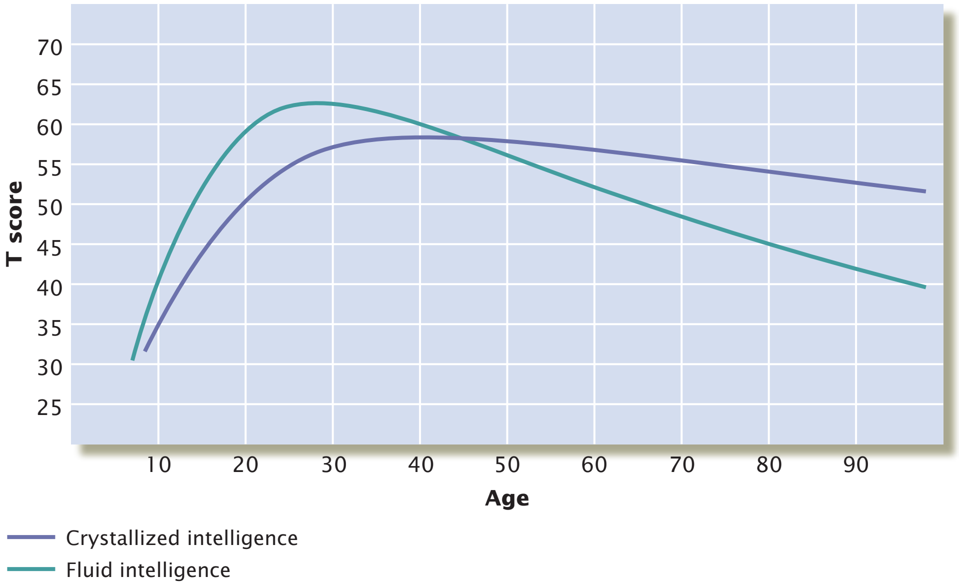

FIGURE 12.7

Mental Abilities over the Life Span

Mental abilities collectively known as "fluid" intelligence—speed and accuracy of information processing, for example—begin to decline quite early in adult life. Changes in these biologically based aspects of thinking are usually not marked until late adulthood, however. "Crystallized" abilities learned over a lifetime—such as reading, writing, comprehension of language, and professional skills—decline too, but later and at a slower pace (Finkel et al., 2007; Li et al., 2004).

Source: Adapted from Baltes (1994).

intact into advanced old age (Freedman, Aykan, & Martin, 2001; Willis & Schaie, 1999). Unfortunately, however, there is one way in which older adults' declining memories can have negative effects: They may be more likely than younger adults to recall false information as being true (Jacoby & Rhodes, 2006; Park, 2001), making some of them prone to victimization by scam artists. For example, the more warnings they hear about a false medical claim—such as that shark cartilage supposedly cures arthritis—the more familiar it becomes, and the more likely they are to believe it. As described in the chapter on memory, younger people are also vulnerable to memory distortions, but they are more likely to remember that false information is false, even when it is familiar.

The decline in cognitive abilities in old age, as well as the rate of that decline, is partly a matter of genetics (Finkel et al., 2009; Reynolds et al., 2005), but other factors are important too. For example, long term use of tobacco or alcohol is associated with reductions in the speed and accuracy of thinking among the elderly and with reductions in IQ (Glass et al., 2006). The risk of cognitive decline is much lower for people who are healthy and psychologically flexible; who eat a healthy diet; who have a high level of education and income and have a satisfying occupation; who live in an intellectually stimulating environment with mentally able spouses or companions; and who had high IQs and were physically active in adolescence (Fritsch et al., 2005; Morris et al., 2006; Yaffe et al., 2009). Scientists speculate that devoting years to obtaining an education and working at a complex job multiplies connections among brain regions and creates "cognitive reserves" that can be drawn on in old age (Hall et al., 2009; Milgram et al., 2006; Springer et al., 2005; Tucker-Drob, Johnson, & Jones, 2009).

Mental exercise—such as doing puzzles, painting, and talking to intelligent friends—also helps older adults continue to think and remember effectively and creatively (Hall et al., 2009; Schooler, 2007). Practice at memory and other information-processing tasks may even lead to some improvement in skills impaired by old age and disuse (Erickson et al., 2007; Kramer & Willis, 2002; Rapp, Brenes, & Marsh, 2002; Tranter & Koutstaal, 2008). Continued physical exercise helps too. A lifetime of fitness through dancing or other forms of aerobic exercise has been associated with better maintenance of skills on a variety of mental tasks, including reaction time, reasoning, and divided attention (Abbott et al., 2004; Baker et al., 2010; McAuley, Kramer, & Colcombe, 2004; Smith et al., 2010; Weuve et al., 2004).

In short, an "engaged lifestyle" filled with volunteer work, travel, and other organized activities that provide opportunities to interact with a variety of individuals—not just family members—seems to provide the best environment for preventing decline in cognitive abilities (Hertzog et al., 2009; Keller-Cohen et al., 2004). Having an optimistic, emotionally stable, extroverted, open, and conscientious personality can help too (Martin et al., 2009). People who believe that they can keep their memories sharp are more likely to use the memory strategies (described in the memory chapter) that help them do just that (Lachman & Andreoletti, 2006). The effect of positive expectations has been demonstrated in the laboratory, where memory performance was better among older adults who were tested after first being exposed to positive words such as *accomplished, alert, knowledgeable,* and *successful* rather than to negative words such as *confused, feeble, forgot,* and *senile* (Hess, Hinson, & Statham, 2004).

The greatest threat to cognitive abilities in late adulthood is *Alzheimer's disease,* which strikes about 10 percent of people over the age of 65 and more than 47 percent of those over 85. As the disease runs its course, parts of these individuals' brains begin to deteriorate (Dauwels et al., 2010; Pengas et al., 2010) and they become emotionally flat, disoriented, and eventually mentally vacant. They usually die prematurely. The average duration of the disease, from onset to death, is seven years. But the age of onset and rate of deterioration depend on a number of factors, such as intelligence (Fritsch et al., 2005; Rentz et al., 2004), gender (Molsa, Marttila, & Rinne, 1995), and education (Mortimer, Snowdon, & Markesbery, 2003). Highly intelligent people show clinical signs of Alzheimer's later than the general population. Women and well-educated people of either gender tend to deteriorate more slowly (Wilson, Scherr, et al., 2007).

Social Changes

In adulthood, people develop new relationships and take on new roles. These changes do not come in neat, predictable stages but instead follow various paths, depending on each individual's experiences. Transitions—such as divorcing, getting fired from a job, going back to school, remarrying, losing a spouse to death, being hospitalized, getting arrested, or retiring—are turning points that can redirect a person's life path and lead to changes in personality (Caspi & Shiner, 2006; Roberts, Helson, & Klohnen, 2002).

Early Adulthood: Work, Marriage, Parenthood Men and women in industrialized cultures typically enter the adult world in their mid to late twenties. At the beginning of this period, about 20 percent of young people are still really emerging adults who live with their parents, and just under half are still financially dependent (Cohen, Kasen, et al., 2003). Gradually, they become more organized, disciplined, and able to plan as they decide on an occupation or at least take a job and become preoccupied with their careers (Srivastava et al., 2003). They also become more agreeable—warmer, more generous and helpful, more controlled and confident; more socially dominant, conscientious, and emotionally stable; and less angry and alienated (Roberts, Caspi, & Moffitt, 2001; Roberts & Mroczek, 2008; Roberts, Walton, & Viechtbauer, 2006; Srivastava et al., 2003).

Young adults become concerned with matters of romantic love. Having reached the sixth of Erikson's stages of psychosocial development noted in Table 12.2 (intimacy versus isolation), they begin to focus on forming mature, committed relationships based on sexual intimacy, friendship, or mutual intellectual stimulation. Those who remain without partners report the lowest levels of happiness, self-esteem, and life satisfaction (Kamp Dush & Amato, 2005). The happiest young adults tend to be those who get married rather than merely live together, go steady, or date casually. Just how willing and able people are to make romantic commitments is predictable in part from the nature of their earlier relations with parents, including the attachment pattern that developed in infancy (Birnbaum et al., 2006; Holland & Roisman, 2010; Treboux, Crowell, & Waters, 2004). Young adults whose view of relationships reflects a secure attachment tend to feel valued and worthy of support and affection. They develop closeness easily and have relationships characterized by joy, trust, and commitment. If their view reflects an insecure attachment, however, they tend to be preoccupied with relationships and may feel misunderstood, underappreciated, and worried about being abandoned. Their relationships are often negative, obsessive, jealous, or promiscuous. Those who develop warm and supportive romantic relationships in early adulthood are likely to have had parents who were accepting and supportive (Conger et al., 2000; Overbeek et al., 2007).

For many young adults, the experience of becoming a parent represents entry into a major new developmental phase that is accompanied by personal, social, and occupational changes (Palkovitz, Copes, & Woolfolk, 2001). This milestone is usually reached earlier for young adults from lower-income backgrounds, who are more likely to be in full-time employment and less likely to be living at home (Cohen, Kasen, et al., 2003). Satisfaction with the marriage or partnership often declines once a baby is born (Doss et al., 2009; Twenge, Campbell, & Foster, 2003). Young mothers may experience particular dissatisfaction, especially if they see their career as important, if parenthood fails to meet their expectations, if they resent the constraints the infant brings, if the infant is temperamentally difficult, if the partnership is not strong, and if their partner is not supportive (Cowan & Cowan, 2000, 2009; Harwood, McLean, & Durkin, 2007; Hogan & Msall, 2002; Jokela, 2010; Shapiro, Gottman, & Carrere, 2000). When the father does not do his share of child care, both mothers and fathers are dissatisfied (Levy-Shiff, 1994). The ability of young parents to provide adequate care for their babies is related to their own childhood histories. New mothers whose attachments to their own mothers were secure tend to be more responsive to their infants, and the infants, in turn, are more likely to develop secure attachments to them (Adam, Gunnar, & Tanaka, 2004; Behrens,

The Transition to Parenthood

Becoming a parent can be a joy, but it may be accompanied by dissatisfaction if it fails to meet a couple's expectations, severely restricts their lives, or uncovers weaknesses in their relationship.

Hesse, & Main, 2007; van IJzendoorn, 1995). Parents who experienced harsh treatment as children are likely to be harsh with their own children; those who had more positive parenting in childhood tend to be kinder to their children (Bailey et al., 2009; Conger, Belsky, & Capaldi, 2009).

The challenges of young adulthood are complicated by the nature of family life today. Forty years ago, about half of North American households consisted of married couples in their twenties and thirties—a breadwinner husband and a homemaker wife—raising at least two children together. This picture now describes only about 23.5 percent of households (Frey, 2003). Today, parents are older because they marry later and wait longer to have children. Many are having children without marrying. About 75 percent of African American women become single mothers, and 11 percent of European American college-educated women in their thirties are also choosing single motherhood, a dramatic increase over past decades (Weinraub, Horvath, & Gringlas, 2002). Most of these women become pregnant "the old-fashioned way," but some are taking advantage of technological advances that allow them to conceive through *in vitro fertilization* (Hahn & DiPietro, 2001).

Many gay men and lesbians are becoming parents too. Some estimates suggest that at least four million families in the United States are headed by openly gay or lesbian adults who became parents by retaining custody of children born in a previous heterosexual marriage, adopting children, or having children through artificial insemination or surrogacy (Patterson, 2002). They face special challenges in making the transition to parenthood. Many of them confront discrimination by health care organizations and employer policies that do not recognize their parental role. They may also experience pervasive hostility, even from members of their own extended families.

Whether homosexual or heterosexual, the 60 percent of mothers who hold full-time jobs outside the home often find the demands of children and career pulling them in opposite directions. Devotion to their jobs leaves many of these mothers feeling guilty about spending too little time with their children (Booth et al., 2002), but placing too much emphasis on home life may reduce their productivity at work and threaten their advancement. This stressful balancing act can lead to anxiety, frustration, and conflicts at home and on the job. It affects fathers too. The husbands of employed women are more involved in child care (Pleck, 2004), and they can be effective caregivers (Parke, 2002), but mothers still do most of the child care and housework (Coltrane & Adams, 2008).

Research indicates that gay and lesbian parents share duties more equally—and are more satisfied with the division of labor—than is typically the case in heterosexual families (Patterson, 2002; Solomon, Rothbaum, & Balsam, 2004).

Nearly half of all marriages in the United States end in divorce, creating yet another set of challenges for adults (Clarke-Stewart & Brentano, 2006). Although it frees people from bad relationships, divorce can leave them feeling anxious, guilty, incompetent, depressed, and lonely. Divorce is correlated with health problems and ultimately with earlier mortality. Often divorce creates new stressors, including money problems, changes in living circumstances and working hours, and for custodial parents, a dramatic increase in housework and child care tasks. One study found that two years after divorcing, most women were happier than they were during the final year of their marriage but more stressed than mothers in two-parent families (Hetherington & Stanley-Hagan, 2002). How effectively divorced people deal with these stressors depends on many factors, including the support they receive from friends and family, their general psychological stability and coping skills, their ability to form new relationships, and the degree to which they remain in conflict with their ex-spouses.

In short, the changes seen in families and family life over the past several decades have made it more challenging than ever to successfully navigate the years of early adulthood.

Middle Adulthood: Reappraising Priorities At around age 40, people go through a *midlife transition* during which they may reappraise and modify their lives and relationships. Many feel invigorated and liberated; some feel upset and have a "midlife crisis." Women who chose a career over a family now hear the biological clock ticking out their last childbearing years. Those who have had children become more independent and oriented toward achievement and events outside the family (Helson & Moane, 1987). For both men and women, the emerging sexuality of their teenage children, the emptiness of the nest as their children leave home, or the declining health of a parent may precipitate a crisis.

Following the midlife transition, the middle years of adulthood are often a time of satisfaction, happiness, and other positive emotions as people enjoy a wide variety of leisure activities, including just spending time with the family (Mroczek & Spiro, 2005; Taylor, 2001). Many people become concerned with producing something that will outlast them—usually through parenthood or job achievements. Erikson called

The "Sandwich" Generation

During their midlife transition, many people feel "sandwiched" between generations—pressured by the social, emotional, and financial needs of their children on one side and of their aging parents on the other (Keene & Prokos, 2007; Wujcik, 2008).

this concern the crisis of **generativity** because people begin to focus on activities that will produce or generate something that might benefit future generations. If they do not resolve this crisis by striking a good balance between generativity and self-centeredness, he suggested, people stagnate. Research shows that after the age of 40, people are indeed more likely to strive for generativity goals (Sheldon & Kasser, 2001; Zucker, Ostrove, & Stewart, 2002). These might include writing a book, helping people in need, developing closer relationships with children, being a good role model for them, acting as a coach or mentor, and trying in other ways to make a lasting contribution to society.

In their fifties, most people become grandparents (Smith & Drew, 2002). This new status often amazes them. For example, a survey of professionals in their fifties found that they could not quite believe they were no longer young (Karp, 1991). Most described themselves as healthy but acknowledged that their bodies were slowing down. At this age, spending time caring for young grandchildren can be stressful. One study found that grandmothers who spent more time providing care for their grandchildren were at increased risk of coronary heart disease (Lee, Colditz, et al., 2003). Overall, the degree of happiness and healthiness people experience during middle adulthood depends on how much control they feel they have over their work, finances, marriage, children, and sex life, as well as on the nature of their personality, how many years of education they completed, and what kind of job they have (Azar, 1996; Griffin, Mroczek, & Spiro, 2006).

"When I was your age, I was an adult."

Most people in their sixties want their children to be independent, so they may have mixed feelings toward children who continue to need financial support during an extended period of emerging adulthood (Pillemer & Suitor, 2002).

Late Adulthood: Retirement and Restriction

Even when they are 65 to 75, most people think of themselves as about thirteen years younger than they are and consider themselves middle-aged, not old (Kleinspehn-Ammerlahn, Kotter-Grühn, & Smith, 2008). They are active and influential politically and socially; they are often physically vigorous. Ratings of life satisfaction, well-being, and self-esteem are, on average, as high as they were during earlier adulthood (Ben-Zur, 2002; Hamarat et al., 2002; Sheldon & Kasser, 2001; Stone et al., 2010). Those most likely to enjoy good physical and mental health in late adulthood are the ones who had lots of parental support during childhood (Shaw et al., 2004); who can accept their feelings, memories, and ways of thinking (Butler & Ciarrochi, 2007); and who can adjust to age-related declines as they come (Cheng, Fung, & Chan, 2009).

Late adulthood is the time when men and women usually retire from their jobs, but many people underestimate older people's ability and willingness to work. This misperception was once translated into laws that forced workers to retire at age 65 regardless of their abilities. Thanks to changes in those laws in the United States and some other countries, most people can now continue working as long as they wish. Being forced to retire can result in psychological and physical problems. In one study of cardiovascular disease, men who retired involuntarily were found to be more depressed, less healthy, and less well adjusted than those who retired voluntarily (Clay, 1996). Such problems may also occur when husbands retire before their wives do (Rubin, 1998). Men tend to view retirement as a time to wind down, whereas women see it as a time to try new things and to reinvent themselves (Helgesen, 1998). In general, it seems, voluntary retirees are more likely to be satisfied with their lives than people who continue, by choice or financial necessity, to work through their sixties and seventies (Moen et al., 2000). Satisfaction is especially likely among those who had made careful financial plans long before retirement (Noone, Stephens, & Alpass, 2009).

More people than ever are reaching old age. In fact, people over 75 make up the fastest-growing segment of the population. This group is twenty-five times larger today than it was a hundred years ago. Today, about one hundred thousand people in the United States are older than 100, and the Census Bureau has predicted that this number will rise to 834,000 by 2050 (Volz, 2000). Old age is not necessarily a time of loneliness and desolation, but it is a time when people generally become more inward-looking, cautious, and conforming (Reedy, 1983). It is a time when people develop coping strategies that increasingly take into account the limits of their control—accepting chronic health

generativity Adult concerns about producing something that may be of benefit to others in the future.

problems and other things they cannot change (Brandtstadter & Renner, 1990). One such coping strategy is to direct attention to positive thoughts, activities, and memories (Charles, Mather, & Carstensen, 2003; Mather et al., 2004). In fact, when older adults are asked to look at pictures of faces portraying various emotions, they spend more time looking at happy faces; people of college-age look longer at fearful faces (Isaacowitz et al., 2006). According to socioemotional selectivity theory (Charles & Carstensen, 2007), this difference occurs because in old age, people become more aware than ever that their time on earth is limited. Accordingly, they regulate their emotions so as to focus more on positive than on negative information. So when experimenters deliberately induce negative emotions in a laboratory situation, older adults are better than younger ones at quickly recovering their previous mood (Kliegel, Jager, & Phillips, 2007).

In old age, people interact with others less frequently, but they enjoy their interactions more (Carstensen, 1997). They find relationships more satisfying, supportive, and fulfilling than they did earlier in life. During the last twenty years of their lives, people gradually restrict their social network to loved ones. As long as there are at least three close friends or relatives in their network, they tend to be content, especially if these relationships are good ones (Litwin & Shiovitz-Ezra, 2006).

The many changes associated with adolescence and adulthood are summarized in "In Review: Milestones of Adolescence and Adulthood."

Able at Eighty

At the age of 80, actor and Academy Award–winning director Clint Eastwood is a famous example of the many people whose late adulthood is healthy and vigorous. And he is not slowing down. His acting remains as riveting as ever, and the films he directs just seem to get better and better.

Death and Dying

In old age, people become increasingly aware that death is approaching. They watch as their friends disappear. They feel their health deteriorating, their strength waning, and their intellectual capabilities declining. A few years or a few months before death, some people experience a sharp decline in mental functioning known as **terminal drop** (Wilson, Beck, et al., 2007).

The awareness of impending death brings about the last psychological crisis, according to Erikson's theory, in which people evaluate their lives and accomplishments and affirm them as meaningful (leading to a feeling of integrity) or meaningless

IN REVIEW Milestones of Adolescence and Adulthood

Age	Physical Changes	Cognitive Changes	Social Events and Psychological Changes
Early adolescence (ages 11–15)	Puberty brings reproductive capacity and marked bodily changes.	Formal operations and principled moral reasoning become possible for the first time.	Social and emotional changes result from growing sexual awareness; adolescents experience mood swings, physical changes, and conflicts with parents.
Late adolescence (ages 16–19)	Physical growth continues.	Formal operations and principled moral reasoning become more likely.	An identity crisis accompanies graduation from high school.
Early adulthood (ages 20–39)	Physical growth continues.	Increases continue in knowledge, problem-solving ability, and moral reasoning.	People choose a job and often a mate; they may become parents.
Middle adulthood (ages 40–65)	Size and muscle mass decrease; fat increases; eyesight declines; reproductive capacity in women ends.	Thought becomes more complex, adaptive, and global.	Midlife transition may lead to change; for most, the middle years are satisfying.
Late adulthood (beyond age 65)	Size decreases; organs become less efficient.	Reasoning, mathematical ability, comprehension, novel problem solving, and memory may decline.	Retirement requires adjustments; people look inward; awareness of death precipitates life review.

1. The greatest threat to cognitive abilities in late adulthood is ____________ disease.
2. Adolescents' ____________ identity may be more defining than their national citizenship.
3. Not stealing because "I might get caught" reflects the ____________ stage of moral reasoning.

(leading to a feeling of despair). People at this stage tend to become more philosophical and reflective. They attempt to put their lives into perspective. They reminisce, resolve past conflicts, and integrate past events. They may also become more interested in the religious and spiritual side of life. This "life review" may trigger anxiety, regret, guilt, and despair, or it may allow people to face their own deaths and the deaths of friends and relatives with a feeling of peace and acceptance (Steinhauser et al., 2008; Torges, Stewart, & Nolen-Hoeksema, 2008).

Even the actual confrontation with death does not have to bring despair and depression. People generally want to be told if they are dying (Hinton, 1967). When death finally is imminent, old people strive for a death with dignity, love, affection, physical contact, and no pain. As they think about death, they are likely to be comforted by their religious faith, their achievements, and the love of their friends and family.

Developmental Trajectories

The life span development we have described is a bit like the flight of an airplane, beginning with a takeoff, cruising along for a while, and eventually entering its final descent. Like aircraft bound for differing destinations, the flight path, or trajectory, of our lives can be long or short, reach high or low altitudes, and be bumpy or smooth. There may be midcourse corrections during flight, of course, but researchers who have tracked developmental trajectories find a remarkable degree of stability from childhood through adulthood on many dimensions. For example, people who are intelligent and have good memories, who are good with numbers or poor at languages, tend to retain these advantages or disadvantages throughout their lifetimes (e.g., Anstey, Hofer, & Luszcz, 2003; Chodosh et al., 2002). Personality and social development also remain consistent (Roberts, Caspi, & Moffitt, 2001; Roberts, Helson, & Klohnen, 2002; Shiner, Masten, & Roberts, 2003). Children who are creative, persistent, enthusiastic about their activities, and motivated to achieve are likely to become adults who take pleasure in their pursuits, enjoy challenges, work hard to succeed, and become effective leaders who handle stress well. Children who take their schoolwork seriously and finish their homework promptly are likely to become adults who are traditional in their views, who plan well, and who are not apt to take risks. Children and adolescents who do well in school and have friends and social skills tend to have good romantic relationships, strong friendships, and occupational success as adults (Roisman et al., 2004; Shiner, Masten, & Roberts, 2003). And those who are psychologically healthy in early adolescence tend to remain so into late adulthood (Jones & Peskin, 2010). In contrast, highly aggressive children are likely to develop academic problems in adolescence and to become anxious and depressed young adults and ultimately antisocial adults as each kind of problem cascades into the next (Masten et al., 2005; Schaeffer et al., 2003). In other words, people tend to stay on relatively consistent developmental paths throughout their lives.

Longevity: The Length of Life

The length of life's trajectory depends on a number of factors. Researchers have discovered, for example, that longevity is greater in women and in people without histories of heavy drinking, smoking, or heart problems (Poon, 2008). It is also related to personality characteristics such as conscientiousness as a child (Friedman et al., 1995a) and curiosity and purpose in life as an adult (Boyle et al., 2009; Swan & Carmelli, 1996). Men tend to live longer if their mother was in the "right" age range (between 20 and 34) when they were born and if they had a higher IQ and higher levels of income and education. Women tend to live longer if they had fewer children and had them at a later point in the "right" age range. Men and women alike tend to live longer if they are religious and, perhaps most important from a genetic standpoint, if members of their extended family were long-lived (Deary & Der, 2005; Smith et al., 2009). In fact, the secret of extreme longevity—one hundred years or more—may lie in a group of genes seen in some people that can slow the aging process (Puca et al., 2001; Willcox et al., 2006, 2009).

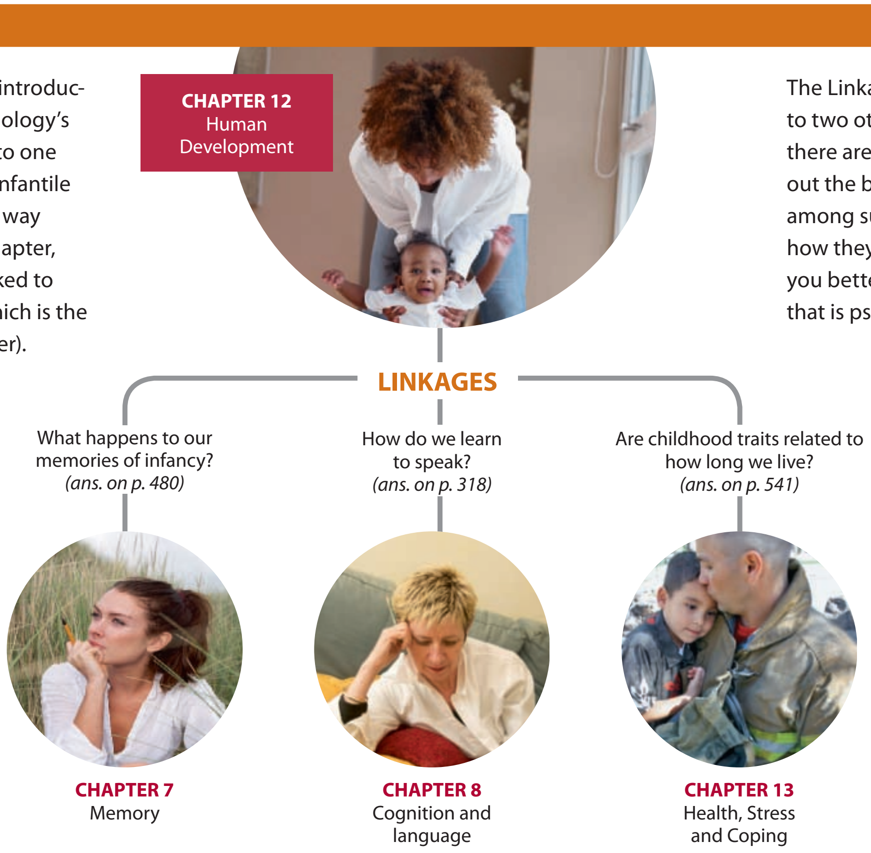
terminal drop A sharp decline in mental functioning that tends to occur in late adulthood, a few years or months before death.

Longer life is also more often seen in people who experienced more happiness, enthusiasm, contentment, and other forms of *positive affect* during adulthood (Cohen & Pressman, 2006; Pressman & Cohen, 2007). Adults who had more positive self-perceptions when they were in their fifties and sixties lived an average of seven and a half years longer than those with less positive self-perceptions. This factor was more predictive of longevity than health problems such as high blood pressure, high cholesterol, smoking, lack of exercise, or being overweight (Levy et al., 2002). A network of good friends, even more than close family ties, is also related to longer life (Giles et al., 2005; Poon, 2008).

Older adults can be made to feel better physically and psychologically if they continue to be socially active and useful. For example, old people who are given parties, plants, or pets are happier and more alert than those who receive less attention, and they do not die as soon (Clark et al., 2001). People who restrict their caloric intake, engage in regular physical and mental exercise, and have a sense of control over important aspects of their lives are also likely to live longer (Manini et al., 2006; Sun et al., 2010; Yaffe et al., 2001). So eat your veggies, stay physically fit, and continue to think actively—not just to live longer later but to live better now.

LINKAGES

As noted in the chapter on introducing psychology, all of psychology's many subfields are related to one another. Our discussion of infantile amnesia illustrates just one way in which the topic of this chapter, human development, is linked to the subfield of memory (which is the focus of the memory chapter).



CHAPTER 12
Human
Development
LINKAGES
What happens to our memories of infancy?
(ans. on p. 480)
How do we learn to speak?
(ans. on p. 318)
Are childhood traits related to how long we live?
(ans. on p. 541)
CHAPTER 7
Memory
CHAPTER 8
Cognition and language
CHAPTER 13
Health, Stress and Coping

The Linkages diagram shows ties to two other subfields as well, and there are many more ties throughout the book. Looking for linkages among subfields will help you see how they all fit together and help you better appreciate the big picture that is psychology.

SUMMARY

Developmental psychology is the study of the course and causes of age-related changes in mental abilities, social relationships, emotions, and moral understanding over the life span.

Exploring Human Development

A central question in developmental psychology concerns the relative influences of nature and nurture, a theme that has its origins in the philosophies of John Locke and Jean-Jacques Rousseau. In the twentieth century, Arnold Gesell stressed nature in his theory of development, proposing that development is *maturation*—the natural unfolding of abilities with age. John B. Watson took the opposite view, claiming that development is learning—shaped by the external environment. In his theory of cognitive development, Jean Piaget described how nature and nurture work together. Today we accept the notion that both nature and nurture affect development and ask how and to what extent each contributes.

Beginnings

Prenatal Development

Development begins with the union of an ovum and a sperm to form a *zygote,* which becomes an *embryo.* The embryonic stage is a *critical period* for development, a time when certain organs must develop properly or they never will. Development of organs at this stage is irrevocably affected by harmful *teratogens,* such as drugs and alcohol. After the embryo develops into a *fetus,* adverse conditions during the fetal stage may harm the infant's size, behavior, intelligence, or health. Babies born to women who drink heavily have a strong chance of suffering from *fetal alcohol syndrome.*

The Newborn

Newborns have limited but effective senses of vision, hearing, taste, and smell. They exhibit many reflexes, which are swift, automatic responses to external stimuli. Motor development proceeds as the nervous system matures, muscles grow, and the infant experiments with and selects the most efficient movement patterns.

Infancy and Childhood: Cognitive Development

Cognitive development includes the development of thinking, knowing, and remembering.

Changes in the Brain

The development of increasingly complex and efficient neural networks in various regions of the brain provides the "hardware" for the increasingly complex cognitive abilities that arise during infancy and childhood.

The Development of Knowledge: Piaget's Theory

According to Piaget, cognitive development occurs in a fixed sequence of stages, as *schemas* are modified through the complementary processes of *assimilation* (fitting new objects or events into existing schemas) and *accommodation* (changing schemas when new objects will not fit existing ones). During the *sensorimotor stage,* infants progress from using only simple senses and reflexes to forming mental representations of objects and actions. Thus the child becomes capable of thinking about objects that are not present. The ability to recognize that objects continue to exist even when they are hidden from view is what Piaget called *object permanence.* During the *preoperational stage,* children can use symbols, but they do not have the ability to think logically and rationally. Their understanding of the world is intuitive and egocentric. They do not understand the logical operations of reversibility or complementarity. When children develop the ability to think logically about concrete objects, they enter the stage of *concrete operations.* At this time, they can solve simple problems. They also have an understanding of *conservation,* recognizing that, for example, the amount of a substance is not altered even when its shape changes. The *formal operational stage* begins in adolescence and allows a wide range of complex executive functions, including planning, imagining consequences, and thinking logically about abstract ideas.

Modifying Piaget's Theory

Research reveals that Piaget underestimated infants' mental abilities. Developmental psychologists now also believe that new levels of cognition are reached not in sharply marked stages of global understanding but more gradually and in specific areas. Children's reasoning is affected by factors such as task difficulty and degree of familiarity with the objects and language involved.

Information Processing During Childhood

Psychologists who explain cognitive development in terms of information processing have documented age-related improvements in children's attention, their abilities to explore and focus on features of the environment, and their memories.

Culture and Cognitive Development

The specific content of cognitive development, including the development of scripts, depends on the cultural context in which children live.

Improving or Endangering Cognitive Development

How fast children develop cognitive abilities depends to a certain extent on how stimulating and supportive their environments are. Children growing up in poverty are likely to have delayed or impaired cognitive abilities.

Infancy and Childhood: Social and Emotional Development

Infants and their caregivers, from the early months, respond to each other's emotional expressions. When an infant's behavior in an ambiguous situation is affected by the caregiver's emotional expression, social referencing is said to have occurred.

Individual Temperament

Most infants can be classified as having an easy, difficult, or slow-to-warm-up *temperament.* Whether they retain their initial temperamental style depends to some extent on their parents' expectations and demands.

Attachment

According to *attachment theory,* over the first year of life, infants form a deep and abiding emotional *attachment* to their mothers or other primary caregivers. Their attachment behavior may be secure or insecure.

Relationships with Parents

The process of *socialization* begins as parents teach their children the skills and rules needed in their culture using various parenting styles. They can be described as *authoritarian, permissive, authoritative,* or *uninvolved* (*rejecting-neglecting*) *parents.* Among European and European American parents, those with an authoritative style tend to have more competent and cooperative children. However, parenting styles and their impact depend to some extent on the culture and conditions in which parents find themselves.

Peer Friendships and Popularity

Over the childhood years, interactions with peers evolve into cooperative and competitive encounters, and friendships become more important.

Social Skills and Understanding

Children become increasingly able to interpret and understand social situations and emotional signals. They begin to express empathy and sympathy and to engage in the *self-regulation* of their emotions and behaviors. They also learn social rules and roles.

Gender Roles

Children develop *gender roles,* also known as *sex roles,* that are based both on biological differences between the sexes and on implicit and explicit socialization by parents, teachers, peers, and the media. Children are also influenced by *gender schemas,* which affect their choices of activities and toys.

Risk and Resilience

Children who lead successful lives despite such adversities as family instability, child abuse, homelessness, poverty, or war are described as having *resilience.* Factors associated with this characteristic include good intellectual functioning and strong relationships with caring adults.

Adolescence

Adolescents undergo significant changes not only in size, shape, and physical capacity but also in their social lives, reasoning abilities, and views of themselves.

Changes in Body, Brain, and Thinking

Puberty brings about physical changes that lead to psychological changes. Changes in the brain alter the ways adolescents think. Specifically, they develop the capacity for formal operational thought and the ability to control their own thinking.

Adolescent Feelings and Behavior

Early adolescence is a period of shaky self-esteem. It is also a time when conflict with parents, as well as closeness with and conformity to friends, is likely to rise. A particularly difficult challenge for adolescents is the transition from elementary school to junior high or middle school.

Identity and Development of the Self

Late adolescence focuses on finding an answer to the question "Who am I?" Adolescents begin to develop an integrated self-image as a unique person, an image that often includes *ethnic identity.*

Moral Development

Principled moral judgment—shaped by gender and culture—becomes possible for the first time in adolescence. The development of moral reasoning may progress through *preconventional, conventional,* and *postconventional reasoning* stages. A person's moral development may be reflected in moral action.

Emerging Adulthood

Going to college challenges the emerging adult's self-concept, precipitating an *identity crisis.* Resolving this identity crisis and choosing a career direction are two major tasks in this stage of life.

Adulthood

Physical, cognitive, and social changes occur throughout adulthood.

Physical Changes

Middle adulthood sees changes that include decreased acuity of the senses, increased risk of heart disease, and the end of fertility (*menopause*). Nevertheless, major health problems may not appear until late adulthood.

Cognitive Changes

The cognitive changes that occur in early and middle adulthood are generally positive, including improvements in reasoning and problem-solving ability. In late adulthood, some intellectual abilities decline—especially those involved in tasks that are unfamiliar, complex, or difficult. Other abilities, such as recalling facts or making wise decisions, tend not to decline. Individuals with Alzheimer's disease become disoriented and mentally vacant, and they die prematurely.

Social Changes

In their twenties, young adults make occupational choices and form intimate commitments. In middle adulthood, they become concerned with *generativity*—with producing something that will outlast them. Sometime around age 40, adults experience a *midlife transition,* which may or may not be a crisis. The forties and fifties are often a time of satisfaction. In their sixties, people contend with retirement. They generally become more inward-looking, cautious, and conforming. Adults' progress through these ages is influenced by the unique personal events that befall them.

Death and Dying

In their seventies and eighties, people confront their own mortality. They may become more philosophical and reflective as they review their lives. A few years or months before death, some individuals experience a sharp decline in mental functioning known as *terminal drop.* They strive for a death with dignity, love, and no pain.

Developmental Trajectories

Researchers who have tracked developmental trajectories have found stability from childhood through adulthood in terms of cognitive abilities, personality characteristics, and social skills.

Longevity: The Length of Life

Death is inevitable, but certain factors—including healthy diets, exercise, personality traits such as conscientiousness and curiosity, a sense of control over one's life, and genetics—are associated with living longer and happier lives. Older adults feel better and live longer if they receive attention from other people, maintain an open attitude toward new experiences, and keep their minds active.

LINKAGES TO FURTHER LEARNING

Now that you have finished reading this chapter, how about exploring some of the topics and information that you found most interesting? Here are some places to start.

Books

Deborah Blum, *Love at Goon Park: Harry Harlow and the Science of Affection* (Perseus, 2002). About Harlow's famous research.

Thomas Hine, *The Rise and Fall of the American Teenager* (Avon, 1999). Social and cultural history of adolescence.

Alison Gopnik, Andrew N. Meltzoff, and Patricia K. Kuhl, *The Scientist in the Crib: Minds, Brains, and How Children Learn* (Morrow, 1999). Readable summary of research in cognitive development.

Rachel Simmons, *Odd Girl Out: The Hidden Culture of Aggression in Girls* (Harcourt, 2002). Study of girls' relational aggression.

Robin Karr-Morse and Meredith S. Wiley, *Ghosts from the Nursery: Tracing the Roots of Violence* (Grove/Atlantic, 1999). How biological predispositions may lead to violence.

TALKING POINTS

Here are a few talking points to help you summarize this chapter for family and friends without giving a lecture.

1. The way we come to think and behave, from childhood to old age, is shaped by a combination of what we inherit at birth and what we experience afterward.
2. We have almost no memories of the time before we were 3 years old, and no one is yet sure why this "infantile amnesia" occurs.
3. Normal social and emotional development requires lots of human contact in the earliest years, which is why the development of orphans who have been neglected is so often impaired.
4. Our temperament at birth can vary from easy to difficult and forms the basis for the development of our personality.
5. Fair but firm parenting tends to be associated with the best outcomes for child development, but there is no single "best" way to raise children.
6. Many people think of adolescence as a time of storm and stress, but most teens navigate this period without suffering major problems.
7. The ability to process information rapidly often begins to decline in late middle age, but most adults retain most of their mental capacities well into old age.

SUMMARY

How long will you live? To some extent, the answer lies in your genes, but it is also affected by how you behave, how you think, and what stressors you face. In this chapter, you will learn about several kinds of stressors, how people respond to them, and the relationship between stress reactions and illness. You'll also discover what you can do to protect your own health.

In Bangor, Maine, where snow and ice have paralyzed the community, Angie's headache gets worse as her 4-year-old daughter and 6-year-old son start bickering again. The day care center and elementary school are closed, so Angie must stay home from her job at the grocery store. She probably couldn't have gotten there anyway, because the buses have stopped running. During the latest storm, the power went out and the house is now almost unbearably cold; the can of spaghetti Angie opens is nearly frozen. Worry begins to creep into her head: "If I can't work, how will I pay for rent and day care?" Her parents have money problems, too, so they can't offer financial help, and her ex-husband rarely makes his child support payments. On top of everything else, Angie is coming down with the flu.

How do people manage such adversity, and what are its consequences for the individual? Psychologists who study questions such as these have established a specialty known as **health psychology** (also called **health care psychology**), "a field within psychology devoted to understanding psychological influence on how people stay healthy, why they become ill, and how they respond when they do get ill" (Taylor, 1999, p. 4).

Health psychologists use knowledge from many subfields of psychology to enhance understanding of the psychological and behavioral processes associated with health and illness (Smith & Suls, 2004). Their work is part of the broader field of *behavioral medicine,* in which psychologists pursue their health-related goals in cooperation with physicians, nurses, public health workers, and other biomedical specialists. In this chapter, we describe some of what has been discovered so far about psychological, social, and behavioral influences on health and how research in health psychology and behavioral medicine is being applied to prevent illness and promote better health. We begin by examining the nature of stressors and people's physical, psychological, and behavioral responses to stress. Then we consider factors that might alter the impact of stressful life events on a person. Next, we consider the psychological factors responsible for specific physical disorders and some behaviors that endanger people's health. We conclude by discussing health psychologists' recommendations for coping with stress and promoting health and some of their programs for doing so.

Health Psychology

Although the field of health psychology is relatively new, the themes underlying it date back to ancient times. For thousands of years, in many cultures around the world, people have believed that their mental state, their behavior, and their health are linked.

Today, there is scientific evidence to support this belief (Schneiderman, 2004; Antoni & Lutgendorf, 2007). We now know that the stresses of life influence health through their impact on psychological and physiological processes. For example, the

Running for Your Life

APPLYING PSYCHOLOGY Health psychologists have developed programs to help people increase exercise, stop smoking, eat healthier diets, and make other lifestyle changes that can lower their risk of illness and death. They have even helped bolster community blood supplies by finding ways to make blood donation less stressful (Bonk, France, & Taylor, 2001).

appearance of physical illness has been associated with anger, hostility, pessimism, depression, social isolation, and hopelessness. Poor health has also been linked to behavioral factors such as lack of exercise, inadequate diet, smoking, and abuse of alcohol and other drugs (Freedman et al., 2006; Mente et al., 2009; van Dam et al., 2008; Vollset, Tverdal, & Gjessing, 2006). Good health, on the other hand, is associated with being optimistic, experiencing positive emotions, and behaviors such as adequate exercise and following medical advice.

Health psychology has become an increasingly important area of research and practice in North America, in part because of changing patterns of illness. Until the middle of the twentieth century, the major causes of illness and death in the United States and Canada were acute infectious diseases, such as influenza, tuberculosis, and pneumonia. With these afflictions now tamed, chronic illnesses—such as coronary heart disease, cancer, and diabetes—have joined stroke, accidents, and injuries as the leading causes of disability and death (Heron, 2007). Compared with acute diseases, these chronic diseases develop more slowly and are more strongly associated with people's psychological makeup, lifestyle, and environment (Centers for Disease Control and Prevention, 2008). For example, whether or not a person smokes affects the risk of the five leading causes of death for men and women in the United States (see Table 13.1). The psychological and behavioral factors that contribute to these illnesses can be changed by intervention programs such as those that promote nonsmoking, physical activity, and healthy eating (e.g., Bazzano et al., 2003; Kraus et al., 2002). In fact, about half the deaths in the United States are due to potentially preventable health risk behaviors (Greenland et al., 2003; Khot et al., 2003; Mokdad et al., 2004). Yet as few as 3 percent of people in the United States follow a lifestyle that includes maintaining a healthy weight, getting regular exercise, eating a proper diet, and not smoking (Reeves & Rafferty, 2005).

One goal of health psychology is to help people understand the role they can play in controlling their own health and life expectancy (Nash et al., 2003; Nicassio, Meyerowitz, & Kerns, 2004). For example, health care psychologists develop programs to educate people about the warning signs of cancer, heart disease, and other serious illnesses; encourage them to engage in self-examinations; and emphasize the importance of seeking medical attention while lifesaving treatment is still possible. Health psychologists also study and help people understand the role played by stress in physical health and illness. And clinical health care psychologists help individuals cope as effectively as possible with cancer, diabetes, heart disease, and many other kinds of serious illness.

TABLE 13.1 Lifestyle Behaviors That Affect the Leading Causes of Death in the United States

This table shows five of the leading causes of death in the United States today, along with behavioral factors that contribute to their development (Centers for Disease Control and Prevention, 2008; Jemal et al., 2005). Worldwide, the number of deaths caused by health-damaging behaviors is expected to continue its upward climb (World Health Organization, 2008).

Understanding Stress and Stressors

You have probably heard that death and taxes are the only two things you can be sure of in life. If there is a third, it must be stress. Health psychologists define **stress** as the internal processes that occur as people try to adjust to events and situations. Stress is woven into the fabric of life. No matter how wealthy, powerful, attractive, or happy you might be, stress happens. The events and situations that create stress are called **stressors**, and they come in many forms: a big exam, an automobile accident, waiting in a long line, reading about frightening world events, or just having a day when everything goes wrong. What all stressors have in common is that they disrupt, or threaten to disrupt, daily functioning and cause people to make adjustments. Stressors can be mild and temporary or severe and long-lasting. Some, such as getting married, having a baby, or landing a better job, can be stimulating, motivating, and desirable. However, when people feel that their stressors exceed their ability to cope, the result can be physical, psychological, and behavioral problems. Stress in the workplace, for example, costs U.S. businesses more than $150 billion each year as a result of employee absenteeism, reduced productivity, and health care costs (Chandola, Brunner, & Marmot, 2006; Schwartz, 2004).

Stress reactions are the physical, psychological, and behavioral responses that occur in the face of stressors (Taylor, 2002). In other words, stress involves a *transaction* between people and their physical and psychological environments. Figure 13.1 lists the main types of stressors and illustrates that when confronted by stressors, people may respond physically (with nausea or fatigue, for example) and psychologically (with anxiety, lack of concentration, or changes in eating habits).

As also shown in Figure 13.1, the transactions between people and their environments can be influenced by *stress mediators*. These mediators include such variables as the extent to which people can predict and control their stressors, how they interpret the threat involved, the amount of social support they perceive as available from family and friends, and their stress-coping skills. (We discuss these mediators in greater detail later.) Mediating factors can either minimize or magnify a stressor's impact. In other words, stress is not a specific event but an ever-changing *process* in which the nature and intensity of our responses depend not only on what stressors occur but also on how we think about them and how much confidence we have in our coping skills and stress-coping resources at any particular time.

Many of our stressors have both physical and psychological components. For example, students are challenged by psychological demands to do well in their courses, as well as by the physical fatigue that can result from a heavy load of classes, combined perhaps with a job and family responsibilities. Similarly, for people with arthritis, AIDS, and other chronic illnesses, pain and fatigue are accompanied by worry and other forms of psychological distress. In the next section, we focus on psychological stressors, which can stimulate some of the same physiological responses as physical stressors (Cacioppo et al., 1995).

stress The internal processes that occur as people try to adjust to events and situations, especially those that they perceive to be beyond their coping capacity.

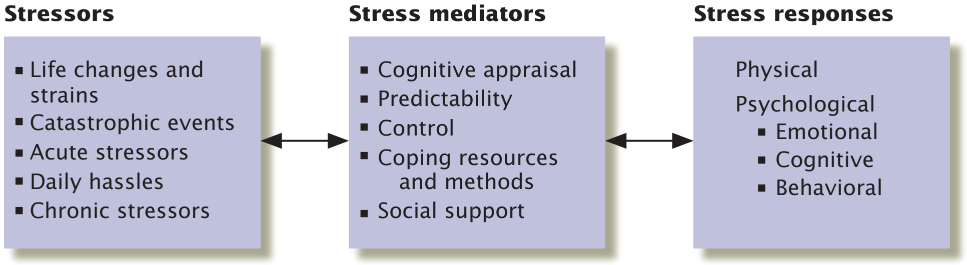
stressors Events or situations to which people must adjust.

stress reactions The physical, psychological, and behavioral responses that occur in the face of a stressor.

FIGURE 13.1

The Process of Stress

Stressful events, stress reactions, and stress mediators are all important components of the stress process. Notice that the process involves many two-way relationships. For example, if a person has effective coping skills, stress responses will be less severe. Having milder stress responses can act as a "reward" that strengthens those skills. Further, as coping skills (such as refusing unreasonable demands) improve, certain stressors (such as a boss's unreasonable demands) may become less frequent.



Psychological Stressors

Any event that forces people to adjust or change can be a psychological stressor. A promotion, for example, can bring higher pay and status, but the increased responsibilities can be a stressor, especially for those who are not sure they can handle the increased pressure (Schaubroeck, Jones, & Xie, 2001). The most adverse psychological stressors are events and situations that are perceived as unpleasant and threatening (Kiecolt-Glaser et al., 2005). These include catastrophic events, life changes and strains, chronic problems, and daily hassles.

Catastrophic events are sudden, unexpected, potentially life-threatening experiences or traumas, such as physical or sexual assault, military combat, natural disasters, terrorist attacks, and accidents. *Life changes* and *strains* include divorce, illness in the family, difficulties at work, and other circumstances that create demands to which people must adjust (see Table 13.2). *Chronic problems*—those that continue over a long period of time—include circumstances such as living in a high-crime neighborhood or under the threat of terrorism, having a serious illness, being unable to earn a decent living, being the victim of discrimination, and even enduring years of academic pressure. *Daily hassles* are irritations, pressures, and annoyances that may not be significant stressors by themselves but whose cumulative effects can be significant (Almeida, 2005; Evans & Wener, 2006).

Measuring Stressors

Which stressors are most harmful? To study stress more precisely, psychologists have tried to measure the impact of particular stressors. In 1967, Thomas Holmes and Richard Rahe (pronounced "ray") made a pioneering effort to find a standard way of measuring the stress in a person's life. Working on the assumption that all change, positive or negative, is stressful, they asked a large number of people to rate—in terms of *life change units* (LCUs)—the amount of change and demand for adjustment associated with events such as divorcing, being fired, retiring, losing a loved one, or becoming pregnant. (Getting married, the event against which raters were told to compare all other stressors, came in as slightly more stressful than losing one's job.) On the basis of these ratings, Holmes and Rahe created the Social Readjustment Rating Scale, or

Coping with Catastrophe

Catastrophic events such as earthquakes, explosions, hurricanes, plane crashes, school shootings, and other traumas are stressors that can be psychologically devastating for victims, their families, and rescue workers. Health psychologists and other professionals provide on-the-spot counseling and follow-up sessions to help people deal with the consequences of trauma.

SRRS. People taking the SRRS receive a stress score equal to the sum of the LCUs for the events they have recently experienced (Holmes & Rahe, 1967).

TABLE 13.2 The Undergraduate Stress Questionnaire

TRY THIS Here are some sample items from the Undergraduate Stress Questionnaire, which asks students to indicate whether various stressors have occurred during the previous week (Crandall, Preisler, & Aussprung, 1992). Check off the items that apply to you, and then make a list of other stressful events you have encountered recently that are not on this list. Keep these stressors in mind as you read the rest of this chapter, and consider whether any of them have led you to experience any of the physical and psychological stress responses described later.

____ Assignments in several classes due the same day
____ Roommate conflict
____ Lack of money
____ Trying to decide on a major
____ Difficulty understanding a professor
____ Staying up late writing a paper
____ Sitting through a boring class
____ Going into a test unprepared
____ Parents getting divorced
____ Problems at the registrar's office

A Daily Hassle

Relatively minor daily hassles can combine to create significant physical and psychological stress responses. The frustrations of daily commuting in heavy traffic, for example, can become so intense for some drivers that they may display a pattern of anger and aggression called "road rage." Between 1990 and 1996, more than ten thousand road rage incidents in the United States alone resulted in 218 deaths and 12,610 injuries (Rathbone & Huckabee, 1999), and the problem continues today.

Numerous studies show that people scoring high on the SRRS and other life change scales are more likely to suffer physical or mental disorders than those with lower scores (e.g., Monroe, Thase, & Simons, 1992). Other researchers questioned, though, whether life changes alone can tell the whole story about the effects of stressors because those changes are only one aspect of the total stress process. Some of those researchers developed scales, such as the Life Experiences Survey, or LES (Sarason, Johnson, & Siegel, 1978), that go beyond the SRRS to measure not just life events but also people's perceptions, or cognitive appraisals, of how positive or negative the events were, how controllable they were, and how well they were able to cope. This information is particularly important for understanding the impact of life experiences that may have different meanings to different individuals. For example, a woman eager to have a child is likely to see pregnancy as a blessing, but for someone who doesn't want a baby or can't afford the costs, a positive pregnancy test can be a significant stressor.

The LES also gives respondents the opportunity to write in and rate any stressors they have experienced that are not on the printed list. This personalized approach is particularly valuable for capturing the differing impact and meaning that experiences may have for men compared with women and for individuals from various cultural or subcultural groups. Divorce, for example, may have very different meanings to people of different religious or cultural backgrounds. Similarly, members of certain ethnic groups are likely to experience stressors—such as prejudice and discrimination—that are not felt by other groups (Flores et al., 2010; Lewis et al., 2006; Matthews et al., 2005; Merritt et al., 2006; Yip, Gee, & Takeuchi, 2008).

Stress Responses

Physical and psychological responses to stress often occur together, especially as stressors become more intense. Furthermore, one type of stress response can set off other types. For example, a physical stress response—such as mild chest pain—may lead to the psychological stress response of worrying about having a heart attack. Still, it is useful to consider each category of stress responses one at a time.

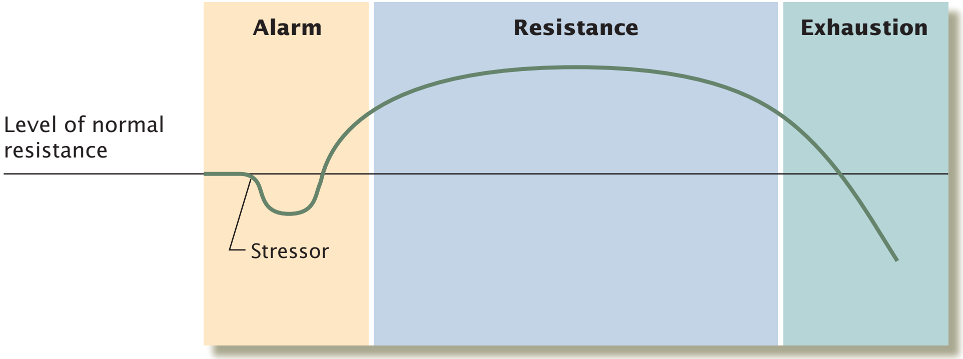

FIGURE 13.2

The General Adaptation Syndrome

Hans Selye found that physical reactions to stressors include an initial alarm reaction, followed by resistance and then exhaustion. During the alarm reaction, the body's resistance to stress temporarily drops below normal as it absorbs a stressor's initial impact. Resistance increases and then levels off in the resistance stage, but it ultimately declines if the exhaustion stage is reached.

Source: Hans Selye, M.D. "The General Adaptation Syndrome" from *Stress Without Distress*. Copyright © 1974 by Hans Selye, M.D. Reprinted by permission of HarperCollins Publishers Inc.

Physical Responses

If you have ever experienced a near accident or some other sudden, frightening event, you know that the immediate physical responses to stressors include rapid breathing, increased heartbeat, sweating, and, a little later, shakiness. These reactions are part of a general pattern known as the *fight-flight reaction* or the *fight-or-flight syndrome.* As described in the chapters on biological aspects of psychology and on motivation and emotion, this syndrome prepares the body to face or flee from an immediate threat. When the danger has passed, the fight-flight reaction subsides (Gump et al., 2005). However, when stressors are long-lasting or when recovery from them is slow, these initial responses are only the beginning of a longer sequence of physical and psychological reactions.

The General Adaptation Syndrome Careful observation of humans and other animals led Hans Selye (pronounced "SEL-yay") to suggest that physical responses to stress occur in a consistent pattern and are triggered by the effort to adapt to any stressor. Selye (1976) called this sequence the **general adaptation syndrome**, or **GAS**. The GAS has three stages, as shown in Figure 13.2.

The first stage is the *alarm reaction,* which involves some version of the fight-or-flight syndrome. In the face of a mild stressor such as an overheated room, the reaction may simply involve changes in heart rate, respiration, and perspiration that help the body regulate its temperature. More severe stressors prompt more dramatic alarm reactions, rapidly mobilizing the body's adaptive energy, much as a burglar alarm alerts the police to take action (Kiecolt-Glaser et al., 1998).

Alarm reactions are controlled by the sympathetic branch of the autonomic nervous system (ANS) through organs and glands that make up the *sympatho-adreno-medullary* (*SAM*) system. As shown on the right side of Figure 13.3, environmental demands (stressors) trigger a process in the brain in which the hypothalamus activates the sympathetic branch of the ANS, which stimulates the medulla (inner part) of the adrenal gland. The adrenal gland, in turn, secretes *catecholamines* (pronounced "kat-uh-KOH-luh-meenz")—especially adrenaline and noradrenaline—which circulate in the bloodstream, activating various organs, including the liver, kidneys, heart, and lungs. The results are increased blood pressure, enhanced muscle tension, increased blood sugar, and other physical changes that provide the energy needed to cope with acute stressors. Even brief exposure to a mild stressor can produce major changes in these coordinated physiological mechanisms (Stoney et al., 2002).

As shown on the left side of Figure 13.3, stressors also activate the *hypothalamic-pituitary-adrenocortical* (*HPA*) *system*, in which the hypothalamus stimulates the

general adaptation syndrome (GAS) A three-stage pattern of responses triggered by the effort to adapt to any stressor.

pituitary gland in the brain. The pituitary, in turn, secretes hormones such as adrenocorticotropic hormone (ACTH). Among other things, ACTH stimulates the cortex (outer surface) of the adrenal glands to secrete *corticosteroids;* these hormones release the body's energy supplies and fight inflammation. The pituitary gland also triggers the release of endorphins, the body's natural painkillers.

The overall effect of these stress systems is to generate emergency energy. The more stressors there are and the longer they last, the more resources the body must expend in response.

If stressors persist, the *resistance stage* of the GAS begins. Here, obvious signs of the initial alarm reaction fade as the body settles in to resist the stressor on a long-term basis. The drain on adaptive energy is slower during the resistance stage than it was during the alarm reaction, but the body is still working hard, physiologically, to cope.

This continued campaign of biochemical resistance is costly. It slowly but surely uses up the body's reserves of adaptive energy. The body then enters the third GAS stage, known as *exhaustion.* In extreme cases, such as prolonged exposure to freezing temperatures, the result is death. More commonly, the exhaustion stage brings signs of physical wear and tear, especially in organ systems that were weak to begin with or that were heavily involved in the resistance process. For example, if adrenaline and cortisol, which help fight stressors during the resistance stage, remain at high levels for an extended time, they can damage the heart and blood vessels. They also suppress the functioning of the body's disease-fighting immune system, leaving people vulnerable

FIGURE 13.3

Organ Systems Involved in the General Adaptation Syndrome

Stressors produce a variety of physiological responses that begin in the brain and spread to organs throughout the body. In the sympatho-adreno-medullary system (SAM; green arrows), for example, the hypothalamus stimulates the release of catecholamines, which mobilize the body for action. Some of these substances may interact with sex hormones to create different physical stress responses and coping methods in men and women (Taylor, Klein, et al., 2000; Taylor et al., 2006). Through the hypothalamic-pituitary-adrenocortical system (HPA; purple arrows), the hypothalamus causes the pituitary gland to trigger the release of endorphins, the body's natural painkillers. The HPA also stimulates the release of corticosteroids, which help resist stress but also tend to suppress the immune system.

to illnesses such as heart disease, high blood pressure, arthritis, colds, and flu (Robles, Glaser, & Kiecolt-Glaser, 2005). Selye referred to illnesses that are caused or worsened by stressors as **diseases of adaptation**.

Psychological Responses

Selye's model has been very influential, but it has also been criticized for underestimating the role of psychological factors in stress, such as a person's emotional state or the way a person thinks about stressors. These criticisms led to the development of *psychobiological models,* which emphasize the importance of psychological as well as biological variables in regulating and producing stress responses (Ganzel, Morris, & Wethington, 2010; Lazarus & Folkman, 1984; Suls & Rothman, 2004). Psychological responses to stress can appear as changes in emotions and thoughts (cognitions), along with changes in behavior.

Emotional Changes The physical stress responses we have described are usually accompanied by emotional stress responses. If someone pulls out a gun and demands your money, you will no doubt experience physiological changes, such as a spike in heart rate, but you will also feel some strong emotion—probably fear, maybe anger. When people describe stress, they are more likely to say, "I was angry and frustrated!" than "My heart rate increased and my blood pressure went up." In other words, they are likely to mention changes in the emotions they are experiencing.

In most cases, emotional stress responses subside soon after the stressors are gone. However, if stressors continue for a long time or occur in a tight sequence, emotional stress reactions may persist. When people do not have a chance to recover their emotional equilibrium, they commonly report feeling tense, irritable, sad, or anxious more and more of the time. In some cases, these reactions can become severe enough to be diagnosed as generalized anxiety disorder, major depressive disorder, or other stress-related problems described in the chapter on psychological disorders.

Cognitive Changes In 1995, in the busy, noisy intensive care unit of a London hospital, a doctor misplaced a decimal point while calculating the amount of morphine a day-old premature baby should receive, and the child died of a massive overdose (Davies, 1999). Reductions in the ability to concentrate, to think clearly, or to

AP Photo/Ali Haider

Another Funeral

Even severe emotional stress responses usually ease eventually, but people plagued by numerous stressful events in quick succession—such as those living in strife-torn areas of the world where violent death is all too frequent—may experience increasingly intense feelings of fear, sadness, and helplessness. These reactions can become severe enough to be diagnosed as generalized anxiety disorder, major depression or other depressive disorder, or other stress-related problems described in the chapter on psychological disorders.

diseases of adaptation Illnesses that are caused or worsened by stressors.

remember accurately are typical cognitive stress reactions (Cavenett & Nixon, 2006; Liston, McEwan, & Casey, 2009; Morgan et al., 2006). Sometimes these problems appear because of *ruminative thinking,* the repeated intrusion of thoughts about stressful events (Lyubomirsky & Nolen-Hoeksema, 1995). Ruminative thoughts about problems in a romantic relationship, for example, can seriously interfere with studying for a test. A related phenomenon is *catastrophizing,* dwelling on and overemphasizing the potential consequences of negative events. During examinations, test-anxious college students are likely to say to themselves, "I'm falling behind," or, "Everyone else is doing better than I am." As catastrophizing or ruminative thinking impairs cognitive functioning, a person may experience anxiety and other emotional arousal that adds to the total stress response and further hampers performance at school or at work (Beilock et al., 2004).

Overarousal created by stressors can also lead to a narrowing of attention, making it harder to scan the full range of possible solutions to complex problems. In fact, stress-narrowed attention may increase the problem-solving errors described in the chapter on cognition and language. People under stress are more likely to cling to *mental sets,* which are well learned but not always efficient approaches to problems. Stress can also intensify *functional fixedness,* the tendency to use objects for only one purpose. Victims of hotel fires, for example, sometimes die trapped in their rooms because in the stress of the moment, it did not occur to them to use the telephone or a piece of furniture to break a window (Renner & Beversdorf, 2010).

Stressors may also impair judgment and decision making (Blanchette & Richards, 2010). People who normally consider all aspects of a situation before making a decision

"Stress for $500, Alex"

The negative effects of stress on memory, thinking, decision making, and other cognitive functions are often displayed by players on quiz shows such as *Jeopardy!* and *Who Wants to Be a Millionaire.* Under the intense pressure of time, competition, and the scrutiny of millions of viewers, contestants may miss questions that seem ridiculously easy to those calmly recalling the correct answers at home.

may, under stress, act impulsively and sometimes foolishly. High-pressure salespeople try to take advantage of this phenomenon by setting a time limit on a special deal, claiming that "supplies are limited" (some TV shopping channels even show a "countdown clock" or an "items remaining" counter) or telling customers that others are waiting to buy the item they are considering (Cialdini, 2001).

Behavioral Responses Clues about people's physical and emotional stress responses come from changes in how they look, act, or talk. Strained facial expressions, a shaky voice, tremors or spasms, and jumpiness are common behavioral stress responses. Posture can also convey information about stress, a fact well known to skilled interviewers.

Even more obvious behavioral stress responses appear as people attempt to escape or avoid stressors. They turn to alcohol, overeat (especially high-fat "comfort" foods), and either sleep too much or skimp on sleep in favor of late-night socializing. These tactics may provide some temporary relief, but they can also have negative health consequences (Cohen et al., 2009; Frone, 2008; Hamer, Molloy, & Stamatakis, 2008; King et al., 2008). In the face of severe or long-lasting stress, some people quit their jobs, drop out of school, or even attempt suicide. In the month after Hurricane Katrina struck the U.S. Gulf Coast in 2005, for example, more than double the normal number of calls were placed from the affected area to the National Suicide Prevention Hotline, and stress-related mental health problems remained long after the storm's immediate effects abated (Breed, 2006; Kessler, Galea, et al., 2008; Roberts et al., 2010). Unfortunately, as discussed in the chapter on learning, escape and avoidance tactics deprive people of the opportunity to learn more adaptive ways of coping with stressful environments, including college. Aggression is another common behavioral response to stressors. All too often, this response is directed at members of one's own family (Hellmuth & McNulty, 2008; Polusny & Follette, 1995). So areas devastated by hurricanes and other natural disasters are likely to see not only suicides but also dramatic increases in reports of domestic violence (Curtis, Miller, & Berry, 2000).

LINKAGES When do stress responses become mental disorders? (a link to Psychological Disorders, p. 602)

Stress and Psychological Disorders

Physical, psychological, and behavioral stress responses sometimes appear together in patterns known as *burnout* and *posttraumatic stress disorder.* **Burnout** is an increasingly intense pattern of physical and psychological dysfunction in response to a continuous flow of stressors or to chronic stress situations (Maslach, 2003). As burnout approaches, previously reliable workers or once-attentive spouses may become indifferent, disengaged, impulsive, or accident-prone. They may miss work frequently, oversleep, perform their jobs poorly, abuse alcohol or other drugs, and become irritable, suspicious, withdrawn, depressed, and unwilling to talk about stress or anything else (Fahrenkopf et al., 2008; Taylor, 2002). Burnout is particularly common among individuals who do "people work," such as teachers and nurses, and those who perceive themselves as being treated unjustly by employers (Elovainio, Kivimäki, & Vahtera, 2002; Hoobler & Brass, 2006). Research suggests a direct and causal relationship between burnout and increased risk for mental and physical health problems (Melamed et al., 2006; Shirom, 2003). Each year, it accounts for a significant percentage of occupational disease claims by U.S. workers (Schwartz, 2004).

A different pattern of severe stress reactions is illustrated by the case of "Mary," a 33-year-old nurse who was raped at knifepoint by an intruder in her apartment (Spitzer et al., 1983). In the weeks following the attack, she became afraid of being alone and was preoccupied with the attack and with the fear that it might happen again. She had additional locks installed on her doors and windows but experienced difficulty concentrating and could not immediately return to work. The thought of sex repelled her.

burnout A gradually intensifying pattern of physical, psychological, and behavioral dysfunction in response to a continuous flow of stressors.

Mary suffered from **posttraumatic stress disorder (PTSD)**, a pattern of adverse reactions following a traumatic and threatening event. Among the characteristic reactions are anxiety, irritability, jumpiness, inability to concentrate or work productively, sexual dysfunction, and difficulty in getting along with others. People suffering from PTSD may also experience sleep disturbances, intense startle responses to noise or other sudden stimuli, long-term suppression of their immune systems, and elevated risk of coronary heart disease (Goenjian et al., 2001; Guthrie & Bryant, 2005; Johnson, Westermeyer, et al., 2002; Kawamura, Kim, & Asukai, 2001; Kubzansky et al., 2009). High-tech scanning techniques reveal that PTSD symptoms are accompanied by noticeable changes in brain functioning and even in brain structure (Kitayama et al., 2005).The most common feature of PTSD is reexperiencing the trauma through nightmares or vivid memories. In rare cases, *flashbacks* occur in which the person behaves for minutes, hours, or days as if the trauma were occurring again.

Posttraumatic stress disorder is usually associated with being in military combat or experiencing other traumatic events such as terrorist attacks, assault, rape, or abuse in childhood (e.g., Dohrenwend et al., 2006; Galea et al., 2002; Shalev & Freedman, 2005; Shalev et al., 2006). Researchers now believe, though, that some PTSD symptoms can be triggered—especially in anxiety-sensitive people—by any major stressor, including car accidents, being diagnosed with a life-threatening disease, being stalked, or living in a community threatened by terrorism or a serial killer (Diamond et al., 2010; Kangas, Henry, & Bryant, 2005; Marshall, Miles, & Stewart, 2010; Schulden et al., 2006).

Life Hanging in the Balance

Symptoms of burnout often plague firefighters, police officers, emergency medical personnel, and others who are repeatedly exposed to time pressure, trauma, danger, and other stressors (Fullerton, Ursano, & Wang, 2004; Perrin et al., 2007). Posttraumatic stress disorder can be another result of these conditions, but it can also occur following a single catastrophic event. Surveys taken in the weeks and months following the 9/11 terrorist attacks on the World Trade Center revealed that 7.5 percent of adults and 10.6 percent of children who lived near the devastated area experienced symptoms of PTSD; in many cases, these symptoms persisted for years (DeLisi et al., 2003; Farfel et al., 2008; Galea et al., 2002; Hoven et al., 2005; Simeon et al., 2003). Even higher rates of PTSD symptoms were widely reported by adult survivors of the massive tidal waves that devastated South and Southeast Asia in 2004 (van Griensven et al., 2006).

posttraumatic stress disorder (PTSD) A pattern of adverse and disruptive reactions following a traumatic event.

Posttraumatic stress disorder may appear immediately following a trauma, but the full expression of its symptoms may not appear until weeks later (Andrews et al., 2007; Gilboa-Schechtman & Foa, 2001; Port, Engdahl, & Frazier, 2001). Many people who develop PTSD require professional help, although some seem to recover without it (Bradley et al., 2005; Perkonigg et al., 2005). For most, improvement takes time; for nearly all, the support of family and friends is vital to recovery (Foa et al., 2005). For some people, though, PTSD never appears, even after severe trauma (Breslau et al., 2005). In fact, some people report enhanced psychological growth after surviving a trauma (Zoellner & Maercker, 2006). Researchers are working to discover what protective factors are operating in these individuals and whether those factors can be strengthened through PTSD treatment programs (Bonanno & Mancini, 2008; Haskett et al., 2006; Kolassa et al., 2010). Stress is also thought to play a role in the development of a number of other psychological disorders, including depression and schizophrenia (Cutrona et al., 2005; see the chapter on psychological disorders). The *diathesis-stress model* suggests that certain people are predisposed to these disorders but that whether or not individuals actually display them depends on the frequency, nature, and intensity of the stressors they encounter. If untreated, stress-related mental health problems can threaten physical health, too. For example, depression or anxiety may leave people unmotivated or forgetful when it comes to taking prescribed medication for high blood pressure or other medical conditions they may have. Similarly, some schizophrenia patients develop delusions that doctors, and the medicines they prescribe, will hurt them and thus begin to avoid both. As a result, all these people are likely to be at increased risk for worsening health.

Stress Mediators

Particular people may react to particular stressors in different ways. The stress of combat, for example, is partly responsible for the errors in judgment and decision making that lead to “friendly fire” deaths and injuries in almost every military operation (Adler, 1993). But the stress in these situations disrupts the performance of some people more than others. Why? And why does one individual survive, and even thrive, under the same circumstances that lead another to break down, give up, and burn out? A number of the mediating factors listed in Figure 13.1 help determine how much impact a given stressor will have (Bonanno, 2005; Kemeny, 2003).

How Stressors Are Perceived

As discussed in the chapter on perception, our view of the world depends on which stimuli we attend to and how we interpret, or appraise, them. Any potential stressor, whether it is a crowded elevator or a deskful of work, usually has a more negative impact on those who perceive it as a threat than on those who see it as a challenge (Lazarus, 1999; Maddi & Khoshaba, 2005).

Evidence for the effects of cognitive factors on stress responses comes from both laboratory experiments and surveys (e.g., Abelson et al., 2005). Figure 13.4 shows the results of a classic experiment that demonstrated these effects. In this case, the intensity of physiological arousal during a film depended on how the viewers were instructed to think about the film (Lazarus et al., 1965). In a more recent study, students who were first trained to see the threatening aspects of information showed more emotional arousal to a stressful video than those who had been trained to see information as nonthreatening (Wilson et al., 2006). Similarly, physical and psychological symptoms associated with the stress of airport noise, of being diagnosed with a serious illness, of learning about toxins in local soil, or of living with terrorism threats are more common in people who engage in catastrophic thinking about these problems (Bryant & Guthrie, 2005; Lerner et al., 2003; Matthies, Hoeger, & Guski, 2000; Speckhard, 2002). Those who hold a more

FIGURE 13.4

Cognitive Influences on Stress Responses

Richard Lazarus and his colleagues found that students' physiological stress reactions to a film showing bloody industrial accidents were affected by the way they thought about the film. Those who had been instructed to remain detached from the film (the "intellectualizers") or to think of it as unreal (the "denial" group) were less upset—as measured by sweat-gland activity—than those in an "unprepared" group. These results were among the first to show that people's cognitive appraisal of stressors can affect their responses to those stressors.

optimistic outlook tend to show milder stress responses, better health outcomes, and longer life spans (de Moor et al., 2006; Taylor , Lerner, et al., 2003; Xu & Roberts, 2010).

The influence of cognitive factors weakens somewhat as stressors become more extreme. For example, chronic-pain patients who feel a sense of control over the pain tend to be more physically active, but this effect does not hold for those whose pain is severe (Jensen & Karoly, 1991). Still, even the impact of natural disasters or major stressors such as divorce may be less intense among those who think of them as challenges to be overcome. In other words, many stressful events are not inherently stressful. Their impact depends partly on how people perceive them. An important aspect of this appraisal is the degree to which the stressors are perceived to be predictable or controllable.

Predictability and Control

Why is the threat of terrorism so terrorizing? For one thing, knowing that a particular stressor might occur but being uncertain about whether or when it will occur tends to increase the stressor's impact (Lerner et al., 2003; Sorrentino & Roney, 2000). In other words, *unpredictable* stressors tend to have more impact than those that are predictable (Lazarus & Folkman, 1984; Pham, Taylor, & Seeman, 2001), especially when the stressors are intense and relatively brief. For example, people whose spouses have died suddenly tend to display more immediate disbelief, anxiety, and depression than those who had weeks or months to prepare for the loss (Schulz et al., 2001; Swarte et al., 2003). This is not to say that predictability provides total protection against stressors. Research with animals shows that predictable stressors, even if relatively mild, can be more damaging than unpredictable ones if they occur over long periods of time (Abbott, Schoen, & Badia, 1984).

The *perception of control* can also mediate the effects of stressors. If people can exert some control over them, stressors usually have less impact on health (e.g., Christensen, Stephens, & Townsend, 1998; Krause & Shaw, 2000). Studies of several thousand employees in the United States, Sweden, and the United Kingdom have found that workers who had little or no control over their work environments were more likely to suffer heart disease and other health problems than workers with a high degree of control over those environments (Bosma et al., 1997; Cheng et al., 2000; Spector, 2002). In another study, researchers randomly selected a group of patients awaiting surgery and gave them a full explanation of the procedures that they could expect to undergo, along with information that would help them manage postsurgical pain (Egbert et al., 1964). After the surgery was over, patients who had been given this information and who felt they had at least some control over the pain they experienced not only were better adjusted than patients in a control group who received no special preparation but also healed faster and could be discharged from the hospital sooner. So impressive are findings such as these that it is now standard procedure in many hospitals to help patients manage or control the stress of emergency treatment or the side effects of surgery by providing preparatory information about what to expect during and after a medical procedure, teaching relaxation skills, and allowing patients to control the administration of their pain medication. These strategies have all been shown to help people heal faster and go home sooner (Broadbent et al., 2003; Chamberlin, 2000; Gordon et al., 2005; Kiecolt-Glaser et al., 1998; Ludwig-Rosenthal & Neufeld, 1988).

Simply *believing* that a stressor is controllable, even if it isn't, can also reduce its impact. This effect was demonstrated in a study in which people with panic disorder (discussed in the chapter on psychological disorders) inhaled a mixture of carbon dioxide and oxygen that typically causes them to experience fear and other symptoms of a panic attack (Sanderson, Rapee, & Barlow, 1989). Half the clients were led to believe (falsely) that they could control the concentration of the mixture. Compared with those who believed they had no control, significantly fewer of the "in control" clients experienced full-blown panic attacks during the session, and their panic symptoms were fewer and less severe.

People who feel they have no control over negative events appear especially prone to physical and psychological problems. They often experience feelings of helplessness and hopelessness that may in turn leave them more vulnerable to heart disease and other serious illnesses as well as to mental disorders such as depression (Sarin, Abela, & Auerbach, 2005; Whang et al., 2009). It has even been suggested that a perceived lack of control partly explains why people in lower socioeconomic groups are at somewhat elevated risk for early death (Stringhini et al., 2010; Trumbetta et al., 2010).

Coping Resources and Coping Methods

People usually suffer fewer ill effects from a stressor if they have adequate coping resources and effective coping methods. *Coping resources* include, for example, the money and time to deal with stressful events. So the physical and psychological responses you experience if your car breaks down are likely to be more negative if you are low on cash and pressed for time than if you have money for repairs and the freedom to take a day off from work.

The impact of stressors can also be reduced by the use of effective *coping methods* (Coté & Pepler, 2002). Most of these methods can be classified as either problem-focused or emotion-focused. *Problem-focused* coping involves efforts to alter or eliminate a source of stress, whereas *emotion-focused* techniques are aimed at regulating the negative emotional consequences of the stressor (Folkman et al., 1986). Some people use both kinds of coping. For example, you might deal with the problem of noise from a nearby airport by forming a community action group to push for tougher noise regulations and, at the same time, calm your anger when noise occurs by mentally focusing on the group's efforts to improve the situation (e.g., Hatfield et al., 2002). As mentioned earlier, coping efforts may not always be so adaptive. In the face of a financial crisis or impending exams, for example, some people rely on emotion-focused methods such as using alcohol or other drugs to ease anxiety but take no problem-focused steps to get out of debt or learn difficult material. These emotion-focused strategies may reduce distress in the short run, but the long-term result may be a financial or academic situation that is worse than it was before. Susan Folkman and Richard Lazarus (1988) have devised a widely used questionnaire to assess the specific ways in which people cope with stressors; Table 13.3 shows some examples of responses to their questionnaire.

TABLE 13.3 Ways of Coping

TRY THIS Coping is defined as the cognitive and behavioral efforts to manage specific demands that people perceive as taxing their resources (Folkman et al., 1986). This table illustrates two major approaches to coping measured by the Ways of Coping questionnaire: problem-focused and emotion-focused coping. Ask yourself which approach you usually take when faced with stressors. Now rank the coping skills listed under each major approach in terms of how often you tend to use each of them. Do you rely on just one or two, or do you adjust your coping strategies to fit different kinds of stressors?

Coping Skills	Example
Problem-focused coping	
Confronting	"I stood my ground and fought for what I wanted."
Seeking social support	"I talked to someone to find out more about the situation."
Planful problem solving	"I made a plan of action, and I followed it."
Emotion-focused coping	
Self-controlling	"I tried to keep my feelings to myself."
Distancing	"I didn't let it get to me; I tried not to think about it too much."
Positive reappraisal	"I changed my mind about myself."
Accepting responsibility	"I realized I brought the problem on myself."
Escape/avoidance (wishful thinking)	"I wished that the situation would go away or somehow be over with."

Sources: Folkman et al. (1986); Taylor (2002).

Particularly when a stressor is difficult to control, it is sometimes helpful to express fully and think about the emotions you are experiencing in relation to the stressful event (Langens & Schüler, 2007; Niederhoffer & Pennebaker, 2002). The benefits of this cognitive strategy have been observed among many individuals whose religious beliefs allow them to bring meaning to the death of a loved one or the devastation of a natural disaster, events that might otherwise seem to be senseless tragedies (Heppner et al., 2006; Powell, Shahabi, & Thoresen, 2003; Tallman, Altmaier, & Garcia, 2007). And when cancer patients are encouraged to express their feelings about their diagnosis and to search for positive aspects of their illness (such as bringing their family closer together), they experience fewer symptoms, need fewer medical visits, and adjust better to their disease (Antoni et al., 2001; Low, Stanton, & Danoff-Burg, 2006). Humor may also play a role. Some individuals who use humor to help them cope show better adjustment and milder physiological reactivity to stressful events (Martin, 2001; Moran, 2002).

Social Support

Has a good friend ever given you comfort and reassurance during troubled times? If so, you have experienced the value of *social support* in easing the impact of stressful events. **Social support** consists of emotional, tangible, or informational resources provided by other people. These people might help eliminate a stressor (by, say, helping you fix your car), suggest how to deal with the stressor (by recommending a good mechanic), or reduce a stressor's impact by providing companionship and reassurance that you are cared about and valued and that everything will be all right (Sarason, Sarason, & Gurung, 1997). The people you can depend on for support make up your network of social support (Burleson, Albrecht, & Sarason, 1994).

The stress-reducing effects of social support have been documented for a wide range of stressors, including cancer, stroke, military combat, loss of loved ones, natural

social support The network of friends and social contacts on whom one can depend for help in dealing with stressors.

You've Got a Friend

Even when social support cannot eliminate stressors, it can help people, such as these cancer survivors, feel less anxious, more optimistic, more capable of control, and more willing to try new ways of dealing with stressors (Trunzo & Pinto, 2003). Those who provide social support may feel better too (Brown et al., 2003).

© Manchan/Photographer's Choice RF/Getty Images

disasters, arthritis, AIDS, and even ethnic discrimination (e.g., Antoni & Lutgendorf, 2007; Boden-Albala et al., 2005; Foster, 2000; Jason, Witter, & Torres-Harding, 2003; Penner, Dovidio, & Albrecht, 2001; Savelkoul et al., 2000; Weihs, Enright, & Simmens, 2008). Social support can have health benefits too. For example, students who get emotional support from friends show better immune system functioning than those with less adequate social support (Cohen & Herbert, 1996). This may be why people in strong social support networks are less vulnerable to colds and flu during exams and other periods of high academic stress (Kop et al., 2005; Pressman et al., 2005; Taylor, Dickerson, & Klein, 2002). Having strong social support is also associated with faster recovery from surgery or illness, possibly because helpful friends and family members encourage patients to follow medical advice (Brummett et al., 2005; Krohne & Slangen, 2005; Taylor, 2002). People in stronger social networks—especially those filled with happy people—tend to be happier than those in weaker networks and may even enjoy better mental functioning in old age (Barnes et al., 2004; Fowler & Christakis, 2008). According to some researchers, having inadequate social support can be as dangerous as smoking, obesity, or lack of exercise in that it nearly doubles a person's risk of dying from disease, suicide, or other causes (House, Landis, & Umberson, 1988; Kiecolt-Glaser & Newton, 2001; Rutledge et al., 2004).

Exactly how social support brings about its positive effects is not entirely clear. James Pennebaker (1995, 2000) has suggested that social support may help prevent illness by providing the person under stress with an opportunity to express pent-up thoughts and emotions. In fact, keeping important things to yourself can itself be a stressor (e.g., Dalgleish, Hauer, & Kuyken, 2008; Srivastava et al., 2009). One laboratory experiment found that participants who were asked to deceive an experimenter showed elevated physiological arousal (Pennebaker & Chew, 1985). Other studies suggest that if the spouses of people who die as the result of an accident or suicide do not or cannot confide their feelings to others, they are especially likely to develop physical illness during the year following the spouse's death (Pennebaker & O'Heeron, 1984). Disclosing (even anonymously) the stresses and traumas one has experienced is associated with enhanced immune functioning, reduced physical symptoms, and decreased use of health services (Broderick, Junghaenel, & Schwartz, 2005; Campbell & Pennebaker, 2003; Epstein, Sloan, & Marx, 2005; Pachankis & Goldfried, 2010). This

Fighting a Deadly Disease

The impact of psychological factors on immune system functioning can be seen in the progression of HIV/AIDS. Sustained depression, concealment of gay identity, negative expectancies, and reliance on passive, emotion-focused coping methods such as denial have all been related to faster disease progression. Openly expressing emotions, collaborating closely with doctors, having optimistic expectations, remaining involved in normal activities, finding meaning in the situation, and other active, problem-focused coping strategies have all been associated with slower disease progression (Balbin, Ironson, & Solomon, 1999).

may explain why support groups for a wide range of problems such as bereavement, overeating, and alcohol and drug abuse tend to promote participants' physical health (Taylor et al., 2002).

Research in this area is made more challenging by the fact that the relationship between social support and the impact of stressors is not a simple one. For one thing, the quality of social support may influence people's ability to cope with stress, but the reverse may also be true: Your ability to cope may determine the quality of social support you receive (McLeod, Kessler, & Landis, 1992). People who complain endlessly about stressors but never try to do anything about them may discourage social support, whereas those with an optimistic, action-oriented approach may attract support.

Second, *social support* refers not only to relationships with others but also to the recognition that others care and can be depended on to help (Demaray & Malecki, 2002). If some relationships in a seemingly strong social support network are actually stormy and fragile, they can create interpersonal conflicts that undermine confidence in the dependability of support. The resulting uncertainly can have an adverse effect on health (Ben-Ari & Gil, 2002; Malarkey et al., 1994).

Third, having too much support or the wrong kind of support can be as bad as not having enough (Reynolds & Perrin, 2004). Dangerous behaviors such as smoking or overeating, for example, can be harder to give up if one's social support consists largely or entirely of smokers or overeaters (Christakis & Fowler, 2007). People whose friends and family overprotect them from stressors may actually put less energy into coping efforts or have less opportunity to learn effective coping strategies. In one study of people with physical disabilities, nearly 40 percent of them were found to have experienced emotional distress in response to the well-intentioned help they received from their spouses. This distress, in turn, was a predictor of depression nearly a year later (Newsome & Schulz, 1998). Similarly, people living in crowded conditions may at first perceive the situation as providing lots of social support, but these conditions may eventually become an added source of stress (Lepore, Evans, & Schneider, 1991).

Finally, the value of social support may depend on the kind of stressor being encountered. So although having a friend present might reduce the impact of some stressors, it might amplify the impact of others. Researchers have found, for example, that individuals preparing to speak in public or endure other social stress situations experienced stronger physical and psychological stress responses when a friend or a supportive audience was watching than when they were alone (Stoney & Finney, 2000; Taylor et al., 2010). In short, the efforts or presence of members of a social support network can sometimes become annoying, disruptive, or interfering, thereby increasing stress and intensifying psychological problems (Newsome, 1999; Ruiz et al., 2006). It has even been suggested that among people under intense stress, the benefits of having a large social support network may be offset by the dangers of catching a cold or the flu from people in that network (Hamrick, Cohen, & Rodriguez, 2002).

Stress, Personality, and Gender

The impact of stress on health appears to depend not only on how people think about particular stressors but also to some extent on how they think about and react to the world in general. For instance, stress-related health problems tend to be especially common among people whose "disease-prone" personalities lead them to try to ignore stressors when possible; perceive stressors as long-term, catastrophic threats that they brought on themselves; and be pessimistic about their ability to overcome stressors (e.g., Penninx et al., 2001; Roy et al., 2010; Segerstrom et al., 1998; Suinn, 2001).

Other cognitive styles, such as those characteristic of "disease-resistant" personalities, help insulate people from the ill effects of stress. These people tend to think of stressors as temporary challenges to be overcome, not catastrophic threats, and they do not constantly blame themselves for bringing them about. One particularly important component of the disease-resistant personality is *dispositional optimism*, the belief or expectation that things will work out positively (Folkman & Moskowitz, 2000; Rosenkranz et al., 2003; Taylor, Kemeny, et al., 2000). Optimistic people tend to live longer (Giltay et al., 2004, 2006), to experience fewer health consequences following major stressors, and to have more resistance than pessimists to colds and other infectious diseases (Cohen et al., 2003a, 2003b; Kivimäki et al., 2005; Pressman & Cohen, 2005; Segerstrom & Sephton, 2010). These data help explain why optimistic students experience fewer physical symptoms at the end of the academic term (Aspinwall & Taylor, 1992; Ebert, Tucker, & Roth, 2002). Optimistic coronary bypass surgery patients tend to heal faster and stay healthier than pessimists (Scheier et al., 1989) and to experience a higher quality of life following their surgery than those with less optimistic outlooks (Fitzgerald et al., 1993). And among HIV-positive men, dispositional optimism has been associated with less psychological distress, fewer worries, and lower perceived risk of developing full-blown AIDS (Johnson & Endler, 2002; Taylor et al., 1992). These effects appear due in part to optimists' tendency to use challenge-oriented, problem-focused coping strategies that attack stressors directly, in contrast to pessimists' tendency to use emotion-focused coping, such as denial and avoidance (Bosompra et al., 2001; Brenes et al., 2002; Moskowitz et al., 2009). They also tend to be happier than pessimists, a tendency associated not only with less intense and less dangerous physiological responses to stressors but also with greater success in life (e.g., Lyubomirsky, King, & Diener, 2005; Steptoe, Wardle, & Marmot, 2005).

Indeed, like optimism, happiness and other positive emotions, such as hope and curiosity, have been associated with better health and longer life (Cohen et al., 2003a; Ong et al., 2006; Ostir et al., 2006; Richman et al., 2005; Xu & Roberts, 2010). For example, a long-term study of Catholic nuns found that those who wrote with the most positive emotional style when they were young lived longer than those whose writing contained less positive emotions (Danner, Snowden, & Friesen, 2001). Studies like these represent a new line of research in health psychology that focuses on investigating and promoting the positive emotions, behaviors, and cognitive styles associated with better health (Kashdan & Rottenberg, 2010; Seligman, Steen, et al., 2005).

Gender may also play a role in responses to stress (Goldstein et al., 2010). In a review of two hundred studies of stress responses and coping methods, Shelley Taylor and her colleagues found that males under stress tended to get angry, avoid stressors, or both, whereas females were more likely to help others and to make use of their social support networks (Taylor, Klein, et al., 2000; Taylor et al., 2002). Further, in the face of equally intense stressors, men's physiological responses, including changes in heart rate and blood pressure, tend to be more intense than women's (Stoney et al., 1988). This is not true in every case, of course (Smith et al., 2008), but why should a significant difference show up at all? Though the gender role learning discussed in the chapter on human development surely plays a part (Eagly & Wood, 1999), Taylor proposes that women's "tend-and-befriend" style differs from the "fight-or-flight" pattern so often seen in men because of gender differences in how hormones combine under stress. Consider oxytocin (pronounced "ahk-see-TOH-sin"), a hormone released in both sexes as part of the general adaptation syndrome (Taylor et al., 2006; Uvnas-Moberg, Arn, & Magnusson, 2005). Taylor suggests that oxytocin may interact differently with male and female sex hormones: It amplifies physical responses to stressors in men but reduces those responses in women (Light et al., 2005). This gender difference could lead to the more intense emotional and behavioral stress responses typical of men, and it may be partly responsible for men's greater vulnerability to heart disease and other stress-related illnesses (Kajantie & Phillips, 2006). If that is the case, gender differences in stress responses may help explain why women in industrialized societies live an average of five to ten years longer than men (Hoyert, Kung, & Smith, 2005; Kajantie, 2008). The role of gender-related hormones in responding to stress is supported by the fact that there are few, if any, gender differences in children's stress responses. Those differences begin to appear only around adolescence, when the influences of sex hormones become pronounced (Allen & Matthews, 1997).

FOCUS ON RESEARCH METHODS

Personality and Health

LINKAGES Are childhood traits related to how long we live? (a link to Human Development, p. 517)

The way people think and act in the face of stressors, the ease with which they attract social support, and their tendency to be optimists or pessimists are but a few aspects of their *personalities.*

What was the researchers' question?

Are there other personality characteristics that protect or threaten people's health? This was the research question asked by Howard Friedman and his associates (Friedman, 2000; Friedman et al., 1995a, 1995b). In particular, they attempted to identify aspects of personality that increase the likelihood of premature death from heart disease, high blood pressure, or other chronic diseases.

How did the researchers answer the question?

Friedman suspected that an answer might lie in the Terman Life Cycle Study of Intelligence, which was named after Louis Terman, author of the Stanford-Binet intelligence test. As described in the chapter on cognitive abilities, the study was originally designed to document the long-term development of 1,528 gifted California children (856 boys and 672 girls)—nicknamed the "Termites" (Terman & Oden, 1947).

Starting in 1921 and every five to ten years thereafter, Terman's research team gathered information about the Termites' personality traits, social relationships, stressors, health habits, and many other variables. The data were collected through questionnaires and interviews with the Termites themselves, as well as with their teachers, parents, and other family members. When, by the early 1990s, about half of the Termites had died, Friedman realized that the Terman Life Cycle Study could serve as a longitudinal study in health psychology. As in most such studies, the independent variable (in this case, personality characteristics) was not actually manipulated (the Termites had obviously not been randomly assigned different personalities by the researchers), but the various personality traits identified in these people could still be related to a dependent variable (namely, how long they lived). So Friedman and his colleagues gathered the death certificates of the Termites, noted the dates and causes of death, and then looked for associations between personality and longevity.

What did the researchers find?

One of the most important predictors of long life turned out to be a personality dimension known as *conscientiousness,* or social dependability (described in the chapter on personality). Termites who in childhood had been regarded as truthful, prudent, reliable, hardworking, and free from vanity tended to live longer than those whose parents and teachers had identified them as impulsive and lacking in self-control.

Friedman and his colleagues also examined the Terman Life Cycle Study data to investigate the relationship between social support and health. They compared the life spans of Termites whose parents had divorced or who had been in unstable marriages themselves with those who grew up in stable homes and who had stable marriages. The researchers found that people who had experienced parental divorce during childhood or who themselves had unstable marriages died an average of four years earlier than those whose close social relationships had been less stressful.

What do the results mean?

Did these differences in personality traits and social support actually cause some Termites to live longer than others? Friedman's research was based mainly on the analysis of correlations, so it is difficult to draw conclusions about what caused the relationships he observed. Still, Friedman and his colleagues searched the Terman data for clues to mechanisms through which personality and other factors might have exerted a causal influence on how long the Termites lived (Peterson et al., 1998). For example, they evaluated the hypothesis that conscientious, dependable Termites who lived socially stable lives may have followed healthier lifestyles than their impulsive and socially stressed age-mates. They found that people in the latter group did indeed tend to eat less healthy diets and were more likely to smoke, drink to excess, or use drugs. However, these behaviors alone did not fully account for their shorter average life spans. Another possible explanation is that conscientiousness and stability in social relationships create a general attitude of caution that goes beyond eating right and avoiding substance abuse. Friedman found some support for this idea in the Terman data. Termites who were impulsive or low on conscientiousness were somewhat more likely to die from accidents or violence than those who were less impulsive. (A similar finding is reported in the Focus on Research Methods section of the personality chapter.)

What do we still need to know?

The Terman Life Cycle Study cannot provide definite answers about the relationship between personality and health. However, it has generated some important clues and a number of intriguing hypotheses to be evaluated in future research with more representative samples of people. Some of that research has already taken place and tends to confirm Friedman's findings about conscientiousness (Hampson et al., 2006; Kern & Friedman, 2008; Roberts et al., 2009; Terracciano et al., 2008). Further, Friedman's decision to reanalyze a set of data on psychosocial development as a way of exploring issues in health psychology stands as a fine example of how a creative researcher can pursue answers to complex questions that are difficult or impossible to study via controlled experiments.

Our discussion of personality and other factors that can alter the impact of stressors should make it obvious that what is stressful for a particular individual is not determined simply by predispositions, coping styles, or situations. (See "In Review: Stress Responses and Stress Mediators.") Even more important are interactions between the person and the situation, the mixture of each individual's coping resources with the specific characteristics of the situations encountered.

IN REVIEW Stress Responses and Stress Mediators

Category	Examples
Responses	
Physical	Fight-flight reaction involves increased heart rate, respiration, and muscle tension as well as sweating and dilated pupils. Activation of SAM and HPA systems releases catecholamines and corticosteroids. Organ systems involved in prolonged resistance to stressors eventually break down.
Psychological	*Emotional:* anger, anxiety, depression, and other emotional states. *Cognitive:* inability to concentrate or think logically, ruminative thinking, catastrophizing. *Behavioral:* aggression and escape/avoidance tactics (including suicide attempts) and health risk behaviors.
Mediators	
Appraisal	Thinking of a difficult new job as a challenge will create less discomfort than focusing on the threat of failure.
Predictability	A tornado that strikes without warning may have a more devastating emotional impact than a long-predicted hurricane.
Control	Repairing a disabled spacecraft may be less stressful for the astronauts doing the work than for their loved ones on earth, who can do nothing to help.
Coping resources and methods	Having no effective way to relax after a hard day may prolong tension and other stress responses.
Social support	Having no one to talk to about a rape or other trauma may amplify the negative impact of the experience.

1. **The friends and family we can depend on to help us deal with stressors are called our ____________ network.**
2. **Fantasizing about winning money is a(n) ____________ focused way of coping with financial stress.**
3. **Sudden, extreme stressors may cause psychological and behavioral problems known as ____________.**

The Physiology and Psychology of Health and Illness

A large body of research in health psychology has focused on the relationship between stress and illness. In the following sections, we focus on some of the ways in which stress can lead, directly or indirectly, to physical illnesses by affecting the *immune system* and the *cardiovascular system*.

Stress, Illness, and the Immune System

The role of physiological stress responses in altering the body's ability to fight disease was demonstrated well over a century ago. On March 19, 1878, at a seminar before the Académie de Médecine de Paris, Louis Pasteur showed his distinguished audience three chickens. One was a healthy bird that had been raised normally. A second bird had been intentionally infected with bacteria but given no other treatment; it was also healthy. The third chicken Pasteur presented was dead. It had been infected with the same bacteria as the second bird, but it had also been stressed by being exposed to cold temperatures. As a result, the bacteria had killed it (Kelley, 1985).

The First Line of Defense

A patrolling immune system cell sends out an extension known as a *pseudopod* (pronounced "SOO-doh-pahd") to engulf and destroy a bacterial cell before alerting more defenders. Psychological stressors can alter immune system functions through a number of mechanisms. For example, they can activate neural connections between the sympathetic nervous system and organs of the immune system through response systems that have direct suppressant effects on immune function. These suppressant effects are due largely to the release of cortisol and other corticosteroid hormones from the adrenal cortex (see Figure 13.3).

Research conducted since Pasteur's time has greatly expanded knowledge about how stressors affect the body's reaction to disease. **Psychoneuroimmunology** is the field that examines the interaction of psychological, social, behavioral, neural, hormonal, and immune system processes that affect the body's ability to defend itself against disease (Ader, 2001).

The Immune System and Illness

The **immune system** is the body's first line of defense against invading substances and microorganisms. It is perhaps as complex as the nervous system and contains as many cells as the brain (Guyton, 1991). Some of these cells are in organs such as the thymus and spleen, while others circulate in the bloodstream, entering tissues throughout the body. Components of the immune system kill or deactivate viruses, bacteria, and other foreign or harmful agents in the body (Simpson, Hurtly, & Marx, 2000). If our immune system is impaired—by stressors, for example—we are left more vulnerable to colds, mononucleosis, and many other infectious diseases (Potter & Zautra, 1997). It is by disabling the immune system that HIV infection leads to AIDS and leaves the HIV-infected person defenseless against other infections or cancers. The immune system can also become overactive, with devastating results. Many chronic, progressive diseases—including arthritis, diabetes, and lupus erythematosus—are now recognized as *autoimmune disorders.* In these cases, cells of the immune system begin to attack and destroy normal body cells (Oldenberg et al., 2000).

An important aspect of the human immune system is the action of the white blood cells, called *leukocytes* (pronounced "LOO-koh-sytss"). These cells are formed in the bone marrow and serve as the body's mobile defense units. Leukocytes are called into action when foreign substances are detected. Among the varied types of leukocytes are *B-cells,* which mature in the bone marrow, and *T-cells,* which mature in the thymus. Generally, T-cells kill other cells and B-cells produce *antibodies,* which are circulating proteins that bind to specific toxins and other foreign cells and begin to deactivate them. *Natural killer cells,* another type of leukocyte, destroy a wide variety of foreign organisms, but they have particularly important antiviral and antitumor functions. Yet another type of immune system cell is the *macrophage* (pronounced "MAK-roh-fayj). Macrophages engulf foreign cells and digest them in a process called *phagocytosis* (pronounced "fag-uh-sy-TOH-siss"), or "eating cells." These scavengers are able to squeeze out of the bloodstream and enter organs, where they destroy foreign cells.

The activity of immune system cells can be either strengthened or weakened by a number of systems, including the endocrine system and the central and autonomic nervous systems. It is through these connections that stress-related psychological and emotional factors can affect the functioning of the immune system. The exact mechanisms by which the nervous system affects the immune system are not yet fully understood, but they appear to involve both indirect and direct connections (Rosenkranz et al., 2003). The brain can influence the activity of the immune system indirectly by altering the secretion of hormones (including cortisol secretion by the adrenal gland) that stimulate receptors in circulating T-cells and B-cells. More direct influences occur as nerves affect immune organs, such as the thymus, where T-cells and B-cells are stored (Felten et al., 1991; Maier & Watkins, 2000).

The Immune System and Stress

Researchers have found that people under stress are more likely than less stressed people to develop infectious diseases and to experience flare-ups of latent viruses responsible for oral herpes (cold sores) or genital herpes. For example, Sheldon Cohen and his colleagues in the United Kingdom (1995) exposed 394 healthy adult volunteers either to one of five respiratory viruses or to a placebo. The participants were then isolated and asked about the number and severity of life stresses they had experienced in the previous year. After controlling for factors such as prior history of colds, exposure to other viruses, and health practices, the researchers found that the more stress the participants had experienced, the greater the likelihood that their exposure to a virus would result in colds and respiratory infections.

psychoneuroimmunology A field of research on the interaction of psychological, social, behavioral, neural, hormonal, and immune system processes that affect the body's defenses against disease.

immune system The body's first line of defense against invading substances and microorganisms.

These findings are supported by other research showing that a variety of stressors lead to suppression of the immune system. The effects are especially strong in the elderly (Penedo & Dahn, 2004), but they occur in everyone (Kiecolt-Glaser et al., 2002). For example, one study found that as first-year law students participated in classes, took exams, and experienced other stressful aspects of law school, they showed a decline in several measures of immune functioning (Segerstrom et al., 1998). Similarly, reduction in natural killer cell activity has been observed in both men and women following the death of a spouse (Irwin et al., 1987), and a variety of immune system impairments have been found in people suffering the effects of prolonged marital conflict, divorce, unemployment, lack of social support, and loneliness (Cohen et al., 2007; Kiecolt-Glaser & Glaser, 1992). Providing care for an elderly relative who is mentally or physically incapacitated is a particularly stressful circumstance that has been reliably shown to diminish immune function (Kiecolt-Glaser et al., 2003, 2005; Vitaliano, Zhang, & Scanlan, 2003).

The relationship between stress and the immune system is especially important in people who are HIV-positive but do not yet have AIDS. Because their immune systems are already seriously compromised, further stress-related impairments could be life-threatening. Research indicates that psychological stressors are associated with the progression of HIV-related illnesses (e.g., Gore-Felton & Koopman, 2008; Heckman et al., 2004). Unfortunately, people with HIV (and AIDS) face a particularly heavy load of immune-suppressing psychological stressors, including bereavement, unemployment, uncertainty about the future, and daily reminders of serious illness. A lack of perceived control and resulting depression can further amplify their stress responses (Sewell et al., 2000).

Stress, Illness, and the Cardiovascular System

Earlier we discussed the role of the sympatho-adreno-medullary (SAM) system in mobilizing the body's defenses during times of threat. Because the SAM system is linked to the cardiovascular system, its repeated activation in response to stressors, especially chronic ones, has been associated with the development of coronary heart disease (CHD), high blood pressure (hypertension), and stroke (Chida & Steptoe, 2009; Krantz & McCeney, 2002). For example, adults in a nationwide sample who reported the strongest and longest-lasting worry about terrorism after 9/11 were three times more likely than less worried people to develop heart problems over the next three years. Even those who reported the most intense temporary distress right after 9/11 were at elevated risk of developing heart problems over those same three years (Holman et al., 2008).

The link between CHD and physical stress responses appears especially strong in people who show intense physiological reactivity to stressors (Ming et al., 2004; Treiber et al., 2001). For example, among healthy young adult research participants, those whose blood pressure rose most dramatically in response to a mild stressor or a series of stressors were the ones most likely to develop hypertension later in life (Light et al., 1999; Matthews et al., 2004).

As also mentioned earlier, these physiological reactions to stressors—and the chances of suffering stress-related health problems—depend partly on personality, especially on how people tend to think about stressors and about life in general. For example, the trait of *hostility*—particularly when accompanied by irritability and impatience—has been associated with the appearance of coronary heart disease (Bunde & Suls, 2006; Day & Jreige, 2002; Krantz & McCeney, 2002; Smith, Uchino, et al., 2007).

THINKING CRITICALLY

Does Hostility Increase the Risk of Heart Disease?

Hostility is characterized by suspiciousness, resentment, frequent anger, antagonism, and distrust of others (Krantz & McCeney, 2002; Williams, 2001). The identification of hostility as a risk factor for coronary heart disease and *myocardial infarction,* or *MI* (commonly known as heart attack), could be an important breakthrough in understanding the chief cause of death in the United States and most other Western nations. But is hostility as dangerous as health psychologists suspect?

© Esbin-Anderson/The Image Works

"You Can't Fire Me—I Quit!"

For a time, researchers believed that anyone who displayed the pattern of aggressiveness, competitiveness, and nonstop work known as "Type A" behavior was at elevated risk for heart disease (Friedman & Rosenman, 1974). More recent research shows, however, that the danger lies not in these characteristics alone but in hostility, a pattern seen in some, but not all, Type A people.

What am I being asked to believe or accept?

Many researchers claim that individuals displaying hostility are at increased risk for coronary heart disease and heart attack (e.g., Bleil et al., 2004; Boyle et al., 2004). This risk, they say, is independent of other risk factors such as heredity, diet, smoking, and drinking.

What evidence is available to support the assertion?

There is evidence that hostility and heart disease are related, but scientists are still not sure what explains that relationship. Some suggest that the risk of CHD and MI may be elevated in hostile people because these people tend to have an unusually strong reaction to stressors, especially when challenged. During interpersonal conflicts, for example, people predisposed to hostile behavior display not only overt hostility but also unusually large increases in blood pressure, heart rate, and other aspects of SAM reactivity (Brondolo et al., 2003; Suls & Wan, 1993). In addition, it takes hostile individuals longer than normal to get back to their resting levels of SAM functioning (Gerin et al., 2006). Like a driver who damages a car by pressing the accelerator and brake pedals at the same time, these "hot reactors" may create excessive wear and tear on the arteries of the heart as their increased heart rate forces blood through tightened vessels (Johnston, Tuomisto, & Patching, 2008). Increased sympathetic nervous system activation not only puts a strain on the coronary arteries but also leads to surges of stress-related hormones from the adrenal glands, including the catecholamines (adrenaline and noradrenaline). High levels of these hormones are associated with increases in cholesterol and other fatty substances that are deposited in arteries and contribute to coronary heart disease (Bierhaus et al., 2003; Stoney & Hughes, 1999). Cholesterol levels do appear to be elevated in hostile people, even when they are not under stress (Dujovne & Houston, 1991; Engebretson & Stoney, 1995).

Hostility might also affect heart disease risk less directly, through its impact on social support. Some evidence suggests that hostile people get fewer benefits from social support than other people do (Lepore, 1995). Failing to use this support, and possibly offending potential supporters in the process, may intensify the impact of stressful events on hostile people. The result may be increased anger, antagonism, and ultimately, additional stress on the cardiovascular system.

Are there alternative ways of interpreting the evidence?

Studies suggesting that hostility causes CHD or MI are not true experiments. Researchers cannot manipulate the independent variable, hostility, by creating it in randomly selected people, nor can they create experimental conditions in which individuals who differ only in terms of hostility are compared on heart disease, the dependent variable. So although the available evidence suggests an association between hostility and heart disease, it cannot confirm that hostility is causing heart disease. Accordingly, we have to consider other possible explanations of the hostility–heart disease relationship.

For example, some researchers suggest that higher rates of heart problems among hostile people are due not to the impact of hostility on autonomic reactivity and hormone surges but rather to a third variable that accounts for the other two. Specifically, genetically determined autonomic reactivity might increase the likelihood of both hostility and heart disease (Krantz et al., 1988). Supporting this alternative interpretation is evidence that people with an inherited predisposition toward strong physiological responses to the stressors of everyday life not only have a higher risk for CHD but also tend to be more hostile (Cacioppo et al., 1998). It is at least plausible, then, that some individuals are biologically predisposed to exaggerated autonomic reactivity and to hostility, each of which is independent of the other.

It has also been suggested that hostility may be only one of many traits linked to heart disease. Depression, hopelessness, pessimism, and anxiety may also be involved (Frasure-Smith & Lespérance, 2005; Kubzansky, Davidson, & Rozanski, 2005; Nicholson, Fuhrer, & Marmot, 2005; Roy et al., 2010; Suls & Bunde, 2005).

What additional evidence would help evaluate the alternatives?

One way to test whether hostile people's higher rates of heart disease are related to their hostility or to a more general tendency toward intense physiological arousal is to examine how hostile individuals react to stressors when they are not angry. Some researchers have done this by observing the physiological reactions of hostile people during the stress of surgery. One study found that even under general anesthesia, hostile people show unusually strong autonomic reactivity (Krantz & Durel, 1983). Because these patients were not conscious, it appears that oversensitivity to stressors, not hostile thinking, caused their exaggerated stress responses. This possibility is supported by research showing that compared with other people, individuals who have strong blood pressure responses to stressors also show different patterns of brain activity during stress (Gianaros et al., 2005).

What conclusions are most reasonable?

Most studies continue to find that among generally healthy people, those who are hostile—especially men—are at greater risk for heart disease and heart attacks than other people (Chida & Steptoe, 2009; Haukkala et al., 2010; Krantz & McCeney, 2002; Stansfeld & Marmot, 2002). However, the picture is probably more complex than researchers first thought; it appears that many interacting factors affect the relationship between hostility and CHD (Sloan et al., 2010).

A more elaborate psychobiological model may be required—one that takes into account that some individuals may be biologically predisposed to react to stress and challenge with hostility and increased cardiovascular activity, each of which can contribute to heart disease; that hostile people may help create and maintain stressors through aggressive thoughts and actions, which can provoke others to be aggressive; and that hostile people are more likely than others to smoke, drink alcohol to excess, overeat, fail to exercise, and engage in other heart-damaging behaviors (Kiecolt-Glaser, 2010).

We must also keep in mind that the relationship between heart problems and hostility may not be universal. Although this relationship appears to hold for women as well as for men and for individuals in various ethnic groups (e.g., Nakano & Kitamura, 2001; Olson et al., 2005; Stoney & Engebretson, 1994; Yoshimasu et al., 2002), final conclusions must await further research that examines the link between hostility and heart disease in other cultures (Finney, Stoney, & Engebretson, 2002).

Promoting Healthy Behavior

Health psychologists are deeply involved in the development of smoking cessation programs, in campaigns to prevent young people from taking up smoking, in alcohol education and obesity prevention efforts, in the prevention of skin cancer through education about sun safety, and in the fight against the spread of HIV infection and AIDS (Albarracín et al., 2008; Buller, Buller, & Kane, 2005; Durantini et al., 2006; Lombard et al., 2010; Morisky et al., 2006; Stice, Shaw, & Nathan, 2006). They have also helped promote early detection of disease. Encouraging women to perform breast self-examinations and men to do testicular self-examinations are just two examples of health psychology programs that can save thousands of lives each year (Taylor, 2002). Health psychologists have also explored the reasons behind some people's failure to follow treatment regimens that are vital to the control of diseases such as diabetes, heart disease, HIV/AIDS, and high blood pressure (Bartlett, 2002; Gonzalez et al., 2004). Understanding these reasons and devising procedures that encourage greater adherence to medical advice could speed recovery, prevent unnecessary suffering, decrease costs, and save many lives (Barclay et al., 2007; Simpson et al., 2006).

health promotion The process of altering or eliminating behaviors that pose risks to health, as well as encouraging healthy behavior patterns.

Efforts to reduce, eliminate, or prevent behaviors that pose health risks and to increase healthy behavior patterns are known as **health promotion** (Smith, Orleans, & Jenkins, 2004). For example, health psychologists have developed programs that teach children as young as 9 to engage in health-enhancing behaviors and avoid health-risk

© Gustavo Gilabert/Corbis

Doctor's Orders

Despite their physicians' instructions, many patients fail to take their blood pressure medication and continue to eat unhealthy diets. Noncompliance with medical advice is especially common when cultural values and beliefs conflict with that advice. Aware of this problem, health psychologists have developed culture-sensitive approaches to health promotion and disease prevention (Kazarian & Evans, 2001).

behaviors. School systems now offer a variety of these programs, including those that give children and adolescents the skills necessary to refuse cigarettes, drugs, and unprotected sex. To meet the more difficult challenge of modifying existing health-threatening behaviors, health psychologists go into workplaces and communities with the goal of helping people adopt healthier lifestyles by altering diet, smoking, and exercise patterns. They also teach stress management techniques (Langenberg et al., 2000; Tuomilehto et al., 2001). These programs can reduce the need for future medical treatment (Blumenthal et al., 2002; Schneiderman et al., 2001) and lead to better health for participants (Lisspers et al., 2005; Orth-Gomér et al., 2009).

Health Beliefs and Health Behaviors

Health psychologists are also trying to understand the thought processes that lead people to engage in health-endangering behaviors and that can interfere with efforts to adopt healthier lifestyles. Their research has led to intervention programs that seek to change these patterns of thinking or at least take them into account. In one study, for example, women who avoid thinking about the risks of breast cancer were more likely to get a mammogram screening after receiving health information that was tailored to their cognitive styles (Williams-Piehota et al., 2005).

As described in the chapter on cognition and language, humans tend to underestimate the likelihood of common outcomes and to overestimate the likelihood of rare events. When this tendency causes people to ignore the dangers of smoking and other health-risk behaviors, the results can be disastrous.

This cognitive approach to health psychology is embodied in various *health belief models.* One of the most influential of these models was developed by Irwin Rosenstock (1974). This model is based on the assumption that people's decisions about health-related behaviors (such as smoking) are guided by four main factors:

1. Perceiving a *personal threat* of, or susceptibility to, developing a specific health problem. (Do you believe that *you* will get lung cancer from smoking?)
2. Perceiving the seriousness of the illness and the consequences of having it. (How serious do *you* think lung cancer is, and what will happen if *you* get it?)
3. Believing that changing a particular behavior will reduce the threat. (Will giving up smoking prevent *you* from getting lung cancer?)
4. A comparison of the *perceived costs* of enacting a health-related behavior change and the *benefits expected* from that change. (Will the reduced chance of getting cancer in the future be worth the discomfort and loss of pleasure associated with not smoking now?)

According to this health belief model, the people most likely to quit smoking would be those who believe that they are at risk for getting cancer from smoking, that cancer is serious and life-threatening, that quitting will reduce their chances of getting cancer, and that the benefits of preventing cancer clearly outweigh the difficulties associated with quitting (McCaul et al., 2006).

Other cognitive factors are emphasized in other health belief models. For example, people generally do not try to quit smoking unless they believe they can succeed. So *self-efficacy,* the belief that one is able to perform some behavior, is an additional consideration in decisions about health behaviors (Armitage, 2005; Bandura, 1992). A related factor is the person's *intention* to engage in a behavior designed to improve health or protect against illness (Albarracín et al., 2001; Schwarzer, 2001; Webb & Sheeran, 2006).

Health belief models have been useful in predicting a variety of health behaviors, including exercise (McAuley, 1992), safe-sex practices (Fisher, Fisher, & Rye, 1995), adherence to doctors' orders (Bond, Aiken, & Somerville, 1992), and having routine vaccinations and mammograms (Brewer et al., 2007; Champion & Huster, 1995).

Changing Health Behaviors: Stages of Readiness

Changing health-related behaviors depends not only on a person's health beliefs but also on that person's readiness to change. According to James Prochaska and his colleagues, the process of successful change occurs in five stages (Prochaska, DiClemente, & Norcross, 1992; Schumann et al., 2005):

1. *Precontemplation.* The person does not perceive a health-related problem and has no intention of changing in the foreseeable future.
2. *Contemplation.* The person is aware of a health-related behavior that should be changed and is seriously thinking about changing it.
3. *Preparation.* The person has a strong intention to change and has made specific plans to do so.
4. *Action.* The person is engaging successfully in behavior change.
5. *Maintenance.* The healthy behavior has continued for at least six months, and the person is using newly learned skills to prevent relapse, or "backsliding."

These stages may actually overlap somewhat; for example, some "precontemplators" may actually be starting to contemplate change (Herzog & Blagg, 2007). In any case, the path from precontemplation through maintenance can be a bumpy one. Usually, people relapse and go through the stages repeatedly before finally achieving stability in the healthy behavior they desire (Polivy & Herman, 2002). Smokers, for example, typically require three to four cycles through the stages over several years before they finally reach the maintenance stage (Piasecki, 2006).

Programs for Coping with Stress and Promoting Health

Improving people's stress-coping skills is an important part of health psychologists' health promotion work (e.g., Keogh, Bond, & Flaxman, 2006). Let's consider a few specific procedures and programs associated with this effort.

Planning to Cope Just as people with money in the bank have a better chance of weathering a financial crisis, those with effective coping skills may escape some of the more harmful effects of intense stress. Like family money, the ability to handle stress appears to come naturally—perhaps even genetically—to some people (Caspi et al., 2010), but coping can also be learned.

The first step in learning to cope with stress is to make a systematic assessment of the degree to which stress is disrupting your life. This assessment involves (1) identifying the specific events and situations, such as conflicts or life changes, that are operating as stressors, and (2) noting the effects of these stressors, such as headaches, lack of concentration, or excessive drinking. Table 13.4 lists the other steps in a program to cope with stress. Notice that the second step is to select an appropriate goal. Should you try to eliminate stressors or try to change your response to them? Knowing the difference between changeable and unchangeable stressors is important. Stress-related problems are especially common among people who either exhaust themselves trying to change unchangeable stressors or miss opportunities to change stressors that can be changed (Folkman, 1984).

Bear in mind, though, that no single method of coping with stressors is right for every person or every stressor. As mentioned earlier, for example, denying the existence of an uncontrollable stressor may be fine in the short run but may eventually lead to problems if no other coping method is used. Similarly, people who rely exclusively on an active problem-solving approach may handle controllable stressors well but find themselves nearly helpless in the face of uncontrollable ones (Murray & Terry, 1999). The most successful stress managers may be those who can adjust their coping methods to the demands of changing situations and differing stressors (Kashdan & Rottenberg, 2010; Taylor, 2002).

LINKAGES How can people manage stress? (a link to Treatment of Psychological Disorders, p. 653)

Developing Coping Strategies Like stress responses, strategies for coping with stress can be cognitive, emotional, behavioral, or physical. *Cognitive coping strategies* involve changing how we think about stressors. These changes include thinking more calmly, rationally, and constructively in the face of stressors and may lead to a more hopeful emotional outlook. For example, students with heavy

TABLE 13.4 Stages in Coping with Stress

Many successful programs for systematically coping with stress guide people through several stages and are aimed at removing stressors that can be changed and at reducing responses to stressors that cannot be changed (Taylor, 2002).

Stage	Task
1. Assessment	Identify the sources and effects of stress.
2. Goal setting	List the stressors and stress responses to be addressed. Designate which stressors are and are not changeable.
3. Planning	List the specific steps to be taken to cope with stress.
4. Action	Implement coping plans.
5. Evaluation	Determine the changes in stressors and stress responses that have occurred as a result of coping methods.
6. Adjustment	Alter coping methods to improve results, if necessary.

course loads may experience anxiety, confusion, discouragement, lack of motivation, and the desire to run away from it all. Frightening, catastrophizing thoughts about their tasks (for example, "What if I fail?") magnify these stress responses. Cognitive coping strategies replace catastrophic thinking with thoughts in which stressors are viewed as challenges rather than threats (Ellis & Bernard, 1985). This substitution process is called *cognitive restructuring* (Lazarus, 1971; Meichenbaum, 1977). It involves first identifying upsetting thoughts (such as "I'll never figure this out!") and then developing and practicing more constructive thoughts to use when under stress (such as "All I can do is the best I can"). Cognitive coping does not eliminate stressors, but it can help people perceive them as less threatening and thus make them less disruptive (Antoni et al., 2001; Chesney et al., 2003).

Finding social support is an effective *emotional coping strategy.* As mentioned earlier, feeling that you are cared about and valued by others can be a buffer against the ill effects of stressors (Taylor, 2002; Taylor, Klein, et al., 2000). Research suggests that having enhanced social support is associated with improved immune function (Kiecolt-Glaser & Newton, 2001) and more rapid recovery from illness (Taylor, 2002).

TRY THIS

Behavioral coping strategies involve changing behavior in ways that minimize the impact of stressors. Time management is one example. If it seems that you are always pressed for time, consider developing a time management plan. The first step is to use a calendar or day planner to record how you spend each hour of each day in a typical week. Next, analyze the information to locate when and how you might be wasting time and how you might use your time more efficiently. Then set out a schedule for the coming week and stick to it. Make adjustments in subsequent weeks as you learn more realistic ways to manage your time. Time management can't create more time, but it can help control catastrophizing thoughts by providing reassurance that there is enough time for everything and a plan for handling all that you have to do.

Dealing with Chemotherapy

Progressive muscle relaxation training can be used to ease a variety of health-related problems. For example, one study found that this training resulted in significant reductions in anxiety, physiological arousal, and nausea following cancer chemotherapy (Burish & Jenkins, 1992).

progressive muscle relaxation training A procedure for learning to relax that involves tensing muscles and then releasing the tension in those muscles.

Physical coping strategies can be used to alter the undesirable physiological responses that occur before, during, or after the appearance of stressors. The most common physical coping strategy is some form of drug use. Prescription medications are sometimes an appropriate coping aid, especially when stressors are severe and acute, such as the sudden death of one's child. However, people who rely on prescribed or nonprescription drugs, including alcohol, to help them face stressors may come to believe that their ability to cope is due to the drug, not to their own skill. This belief can make people more and more psychologically dependent on the drug. Furthermore, the drug effects that blunt stress responses may also interfere with the ability to apply other coping strategies. The resulting loss of perceived control over stressors may make those stressors even more threatening and disruptive.

Nonchemical methods of reducing physical stress reactions and improving health and functioning include progressive muscle relaxation training (Bernstein, Borkovec, & Hazlett-Stevens, 2000; Scheufele, 2000), physical exercise (Anshel, 1996), biofeedback (Nestoriuc, Rief, & Martin, 2008), yoga (Kiecolt-Glaser et al., 2010), meditation, and tai chi (Carlson et al., 2003; Li et al., 2001).

Progressive muscle relaxation training is one of the most popular physical methods for coping with stress. It was developed by Edmund Jacobson (1938) and involves tensing a group of muscles (such as the hand and arm) for a few seconds and then releasing the tension and focusing on the resulting feelings of relaxation. This procedure is repeated for each of sixteen muscle groups throughout the body (Bernstein, Borkovec, & Hazlett-Stevens, 2000). Once people develop some skill at relaxation, they can use it to calm themselves down anywhere and anytime, often without lying down. ("In Review: Methods for Coping with Stress" summarizes our discussion of stress-coping methods.)

IN REVIEW Methods for Coping with Stress

Type of Coping Method	Examples
Cognitive	Thinking of stressors as challenges rather than as threats; avoiding perfectionism
Emotional	Seeking social support; getting advice
Behavioral	Implementing a time management plan; where possible, making life changes to eliminate stressors
Physical	Progressive relaxation training; exercise; meditation

1. Catastrophizing thoughts are best overcome through ____________ coping strategies.

2. The first step in coping with stress is to ____________ the sources and effects of your stressors.

3. True or false: It is best to rely on one basic coping strategy. ____________

LINKAGES

As noted in the chapter on introducing psychology, all of psychology's many subfields are related to one another. Our discussion of posttraumatic stress disorder illustrates just one way in which the topic of this chapter, health, stress, and coping, is linked to the subfield of psychological disorders (which is the focus of the chapter by that name). The Linkages diagram shows ties to two other subfields as well, and there are many more ties throughout the book. Looking for linkages among subfields will help you see how they all fit together and help you better appreciate the big picture that is psychology.

SUMMARY

Health Psychology

The development of *health psychology* (also called *health care psychology*) was prompted by recognition of the link between stress and illness, as well as the role of behaviors such as smoking, in elevating the risk of illness. Researchers in this field explore how psychological factors are related to physical disease and vice versa. Health psychologists also help people behave in ways that prevent or minimize disease and promote health.

Understanding Stress and Stressors

The term *stress* refers in part to *stressors*, which are events and situations to which people must adjust. More generally, stress is viewed as an ongoing, interactive process that takes place as people adjust to and cope with their environment. Stressors may be physical or psychological.

Psychological Stressors

Psychological stressors include life changes and strains, catastrophic events, chronic problems, and daily hassles.

Measuring Stressors

Stressors can be measured by tests such as the Social Readjustment Rating Scale (SRRS) and the Life Experiences Survey (LES), as well as by surveys of daily hassles, but scores on such tests provide only a partial picture of the stress in an individual's life.

Stress Responses

Responses to stressors can be physical or psychological. They can occur alone or in combination, and the appearance of one response can stimulate others.

Physical Responses

Physical stress responses include sympatho-adreno-medullary (SAM) activation, such as increases in heart rate, respiration, and many other processes, as well as hypothalamic-pituitary-adrenocortical (HPA) activation, including the release of corticosteroids. These responses are part of a pattern known as the *general adaptation syndrome*, or *GAS*. The GAS has three stages: alarm, resistance, and exhaustion. The GAS helps people resist stress, but if present too long, it can lead to depletion of physiological resources, as well as to physical illnesses, which Hans Selye called *diseases of adaptation*.

Psychological Responses

Psychological stress responses can be emotional, cognitive, and behavioral. Cognitive stress reactions include ruminative thinking, catastrophizing, and disruptions in the ability to think clearly, remember accurately, and solve problems efficiently. Behavioral stress responses include irritability, aggression, absenteeism, and even suicide attempts. Extreme or chronic stressors can lead to *burnout* or *posttraumatic stress disorder (PTSD).*

Stress Mediators

The fact that different individuals react to the same stressors in different ways can be explained in part by stress mediators, such as the extent to which individuals can predict and control their stressors, how they interpret the threat involved, the social support they get, and their stress-coping skills.

How Stressors Are Perceived

Many stressors are not inherently stressful; their impact depends partly on how people perceive them. In particular, stressors appraised as threats are likely to have greater impact than those appraised as challenges.

Predictability and Control

Knowing that a particular stressor might occur but being uncertain whether it will occur tends to increase the stressor's impact, as does lack of control over stressors.

Coping Resources and Coping Methods

The people most likely to react strongly to a stressor are those whose coping resources and coping methods are inadequate.

Social Support

Social support, which consists of resources provided by other people, can lessen the impact of stressors. The friends and social contacts on whom a person can depend for support constitute that person's network of social support.

Stress, Personality, and Gender

Certain personality characteristics help insulate people from the ill effects of stress. One such characteristic appears to be dispositional optimism, the belief or expectation that things will work out positively. Gender can also play a role in stress responses.

The Physiology and Psychology of Health and Illness

Stress, Illness, and the Immune System

Psychoneuroimmunology is the field that examines the interaction of psychological and physiological processes that affect the body's ability to defend itself against disease. When a person is under stress, some of the hormones released from the adrenal gland, such as cortisol, reduce the effectiveness of the cells of the *immune system* (for example, T-cells, B-cells, natural killer cells, and macrophages) in combating foreign invaders such as viruses.

Stress, Illness, and the Cardiovascular System

Heart disease is a major cause of death in most Western countries, including the United States. People who are hostile appear to be at greater risk for heart disease than other people, possibly because their heightened reactivity to stressors can damage their cardiovascular system.

Promoting Healthy Behavior

The process of altering or eliminating health-risk behaviors and fostering healthy behavior patterns is known as *health promotion*.

Health Beliefs and Health Behaviors

People's health-related behaviors are partly guided by their beliefs about health risks and what they can do about them.

Changing Health Behaviors: Stages of Readiness

The process of changing health-related behaviors may involve several stages, including precontemplation, contemplation, preparation, action, and maintenance. Understanding which stages people are in and helping them move through these stages are important tasks in health psychology.

Programs for Coping with Stress and Promoting Health

To cope with stress, people must recognize the stressors affecting them, note the effects of those stressors, and develop ways of handling them. Important coping skills include cognitive restructuring and using emotional and behavioral means to minimize the intensity and impact of stressors. *Progressive muscle relaxation training* and other physical coping strategies can reduce physical stress reactions. These coping procedures are often part of health psychologists' disease prevention and health promotion efforts.

LINKAGES TO FURTHER LEARNING

Now that you have finished reading this chapter, how about exploring some of the topics and information that you found most interesting? Here are some places to start.

Books

David J. Mahoney, *The Longevity Strategy: How to Live to 100 Using the Brain-Body Connection* (Wiley, 1998). The origins of longevity.

Lance Armstrong and Sally Jenkins, *It's Not About the Bike: My Journey Back to Life* (Berkley Books, 2001). Armstrong focuses on the origins of his surviving a deadly form of cancer.

Lewis B. Puller, *Fortunate Son* (Bantam, 1996). Son of a famous Marine deals with posttraumatic stress and multiple amputations after the Vietnam War.

Tony Cassidy, *Stress, Cognition, and Health* (Routledge, 1999). Summarizes research on the effects of stress on thinking and physical well-being.

Jerrold Greenberg, *Comprehensive Stress Management* (McGraw-Hill, 1999). Ideas for stress management.

Robert M. Sapolsky, *Why Zebras Don't Get Ulcers* (Owl Books, 2004). Describes the stress process, stress-related diseases, and coping skills.

James W. Pennebaker, *Opening Up: The Healing Power of Expressing Emotions* (Guilford Press, 1997). Describes research on the benefits of self-disclosure.

TALKING POINTS

Here are a few talking points to help you summarize this chapter for family and friends without giving a lecture.

1. Our lifestyle, especially as it relates to diet, smoking, alcohol use, and exercise, has a lot to do with how healthy we are and how long we will live.
2. In general, predictable stressors have less impact on us than sudden, unpredictable ones.
3. Daily hassles may not be intense stressors by themselves, but they can combine to create significant negative effects.
4. Over time, the effects of stressors can hurt our disease-fighting immune system and leave us vulnerable to many kinds of illness.
5. The impact of stressors on a particular person depends on a combination of what those stressors are, how long they last, and how stress-prone or disease-prone the person is.
6. Some stressors cannot be eliminated or avoided, but we can reduce their impact by thinking of them as challenges rather than as threats.
7. Having a flexible stress-coping plan is a key factor in minimizing the psychological and physical dangers of stress.

SUMMARY

If you've ever been stuck in a traffic jam, you've probably noticed that some people are tolerant and calm. Others become so fearful and cautious that they worsen the congestion. Still others get so impatient and angry that they may trigger a shouting match or cause an accident. How people handle frustration is just one aspect of their personalities. In this chapter, we examine the concept of personality, review some of the tests that psychologists have developed to measure it, and look at how personality theories and research are being applied in everyday life.

Businesses all over the world lose more than $15 billion each year as a result of employee theft (Bamfield, 2008). Millions more are spent on security and surveillance designed to curb these losses, but it would be far better if companies could simply avoid hiring dishonest employees in the first place. Some firms have tried to screen out potential thieves by requiring prospective employees to take polygraph ("lie detector") tests. As described in the chapter on motivation and emotion, however, these tests may not be reliable or valid. In fact, the federal government of the United States has banned their use in most kinds of employee selection.

Thousands of companies have turned instead to paper-and-pencil "integrity" tests designed to identify job applicants who are likely to steal or behave in other dishonest or irresponsible ways (Berry, Sackett, & Wiemann, 2007). Some of these tests simply ask applicants if they have stolen from previous employers and if they might steal in the future. Such questions can screen out people who are honest about their stealing, but most people who steal would probably also lie to conceal previous crimes or criminal intentions. Accordingly, some companies now use tests to assess applicants' general psychological characteristics and compare their scores with those of current or past employees. Applicants whose characteristics are most like the company's honest employees are hired; those who appear similar to dishonest employees are not.

Can undesirable employee behaviors be predicted on the basis of such tests? To some extent, they can. For example, scores on the Reliability Scale—which includes questions about impulsivity and disruptive behavior during school years—are significantly correlated with a broad range of undesirable activities in the workplace (Hogan, 2006). But psychological tests are far from perfect predictors of those activities (Berry, Sackett, & Wiemann, 2007). Although considerably better than polygraph tests, psychological tests still fail to detect dishonesty in some people, and worse, they may falsely identify some honest people as potential thieves. The best that companies can hope for is to find tests that will help reduce the overall likelihood of hiring dishonest people.

The use of psychological tests to help select honest employees is a more formal version of the process that most of us use when we meet someone new. We observe the person's behavior, form impressions, and draw conclusions—often within just a few seconds (Borkenau & Mauer, 2006)—about how that person will act at other times or under other circumstances. Like the employer, we are looking for clues to *personality*. Although there is no universally accepted definition, psychologists generally view **personality** as the unique pattern of enduring thoughts, feelings, and actions that characterize a person. Personality research, in turn, focuses on understanding the origins or causes of the similarities and differences among people in their patterns of thinking, emotion, and behavior (Carver & Connor-Smith, 2010).

personality The pattern of psychological and behavioral characteristics by which each person can be compared and contrasted with others.

With such a large agenda, personality researchers must incorporate information from many other areas of psychology. In fact, personality psychology lies at the crossroads of all psychological research (Funder, 2007). It is the merging, in a particular individual, of all the psychological, behavioral, and biological processes discussed in this book. To gain a full understanding of anyone's personality, for example, you must know something about that person's developmental experiences (including cultural influences), genetic and other biological characteristics, perceptual and other information-processing habits and biases, typical patterns of emotional expression, and social skills. Psychologists also want to know about personality in general, including how it develops and changes across the life span, why some people are usually optimistic whereas others are usually pessimistic, and how consistent or inconsistent people's behavior tends to be from one situation to the next.

In this chapter, we describe four approaches to the study of personality and some of the ways in which personality theory and research are being applied. We begin by presenting the *psychodynamic approach,* which was developed by Sigmund Freud and later modified by a number of people he influenced. Next, we describe the *trait approach,* which focuses on the consistent patterns of thoughts, feelings, and actions that form individual personalities. Then we present the *social-cognitive approach,* which explores the ways in which learning—and learned ways of thinking—shape human behavior. Finally, we consider the *humanistic approach,* with its emphasis on personality as a reflection of personal growth and the search for meaning in life. After reviewing these approaches, we describe how psychologists measure and compare people's personalities. We also give some examples of how psychological tests are being used in personality research and in other ways as well.

© Mary Evans/Sigmund Freud Copyrights/The Image Works

Founder of the Psychodynamic Approach

Here is Sigmund Freud with his daughter, Anna, who became a psychoanalyst herself and eventually developed a revised version of her father's theories.

The Psychodynamic Approach

Some people think they can understand personality by simply watching people. Someone with an "outgoing personality," for example, shows it by acting friendly and sociable. But is that all there is to personality? Not according to Sigmund Freud. Trained as a medical doctor in the late 1800s, Freud spent most of his life in Vienna, Austria, where he treated patients who displayed "neurotic" disorders, such as blindness or paralysis, for which there was no physical cause. Freud's experience with these patients, as well as his reading of the works of Charles Darwin and other scientists of his day, led him to believe that our personalities and behavior, including disordered behavior, are determined mainly by basic drives and past psychological events (Allen, 2006). He agreed, too, with Sir Francis Galton and other nineteenth-century writers when he proposed that people may not know why they feel, think, or act the way they do because these activities are partly controlled by the unconscious part of the personality—the part of which we are not normally aware (Friedman & Schustack, 2009). From these ideas Freud created the **psychodynamic approach** to personality, which assumes that our thoughts, feelings, and behavior are determined by the interaction of various unconscious psychological processes (Schultz & Schultz, 2009).

psychodynamic approach Freud's view that personality is based on the interplay of unconscious mental processes.

The Structure and Development of Personality

Freud believed that people have certain basic impulses or urges, related not only to food and water but also to sex and aggression. Freud described these impulses and urges with a German word that translates as "instinct," but he did not believe that they are all inborn and unchangeable, as the word *instinct* might imply (Schultz & Schultz, 2009). He did believe, though, that our desires for love, knowledge, security, and the like arise from these more basic impulses. He said that each of us faces the task of figuring out how to satisfy basic urges. Our personality develops, he claimed, as we struggle with that task, and it is reflected in the ways we go about satisfying a range of urges.

FIGURE 14.1

Freud's Model of Personality

According to Freud, some parts of the personality are conscious, while others are unconscious. Between these levels is the *preconscious,* which Freud regarded as the location of memories and other material that is not usually in awareness but that can be brought into consciousness with minimal effort.

Id, Ego, and Superego As shown in Figure 14.1, Freud described the structure of personality as having three major components: the id, the ego, and the superego (Carver & Scheier, 2008).

He regarded the **id** as the unconscious portion of personality, in which two kinds of "instincts" reside. There are life instincts, which he called *Eros*. They promote positive, constructive behavior and reflect a source of energy (sometimes called *psychic energy*) known as **libido**. There are also death instincts, or *Thanatos,* which Freud perceived as responsible for aggression and destructiveness (Hergenhahn & Olson, 2007). The id operates on the **pleasure principle**, seeking immediate satisfaction of both kinds of instincts, regardless of society's rules or the rights or feelings of others. The hungry person who pushes to the front of the line at Burger King would be satisfying an id-driven impulse.

Children's expression of their id impulses are soon increasingly restricted by parents, teachers, and others. In the face of these restrictions, a second part of the personality—the **ego**—develops from the id. The ego tries to find ways to get what a person wants in the real world, as opposed to the fantasy world of the id. Operating on the **reality principle**, the ego makes compromises between the id's unreasoning demands for immediate satisfaction and the practical limits imposed by the social world. The ego would lead that hungry person at Burger King to wait in line and think about what to order rather than risk punishment by pushing ahead.

As children learn about the rules and values of society, they tend to adopt them. This process of *internalizing* parental and cultural values produces the third component of personality. It is called the **superego**, and it tells us what we should and should not do. The superego becomes our moral guide, and it is just as relentless and unreasonable as the id in its demand to be obeyed. It would make the hungry person at Burger King feel guilty for even thinking about violating society's rules.

Conflicts and Defenses Freud described the inner clashes among the three personality components as *intrapsychic* or *psychodynamic conflicts*. He believed that each person's personality is shaped by the number, nature, and outcome of these conflicts. Freud said that the ego's primary function is to prevent the anxiety or guilt we would feel if we became aware of our socially unacceptable id impulses or if we thought about violating the superego's rules (Westen et al., 2008). Sometimes the ego motivates sensible actions, as when a parent asks for help in dealing with impulses to abuse a child. However, the ego may also use **defense mechanisms**, which are unconscious tactics that protect against anxiety and guilt by either

id The unconscious portion of personality that contains basic impulses and urges.

libido The psychic energy contained in the id.

pleasure principle The id's operating principle, which guides people toward whatever feels good.

ego The part of the personality that mediates conflicts between and among the demands of the id, the superego, and the real world.

reality principle The operating principle of the ego that creates compromises between the id's demands and those of the real world.

superego The component of personality that tells people what they should and should not do.

defense mechanisms Psychological responses that help protect a person from anxiety and guilt.

TABLE 14.1 Ego Defense Mechanisms

TRY THIS According to Freud, defense mechanisms prevent or deflect anxiety or guilt in the short run, but they sap energy. Further, using them to avoid dealing with the source of problems can make those problems worse in the long run. Try listing some incidents in which you or someone you know may have used each of the defenses described here. What questions would a critical thinker ask to determine whether these behaviors were unconscious defense mechanisms or actions motivated by conscious intentions?

Defense Mechanism	Description	Example
Repression	Unconsciously pushing threatening memories, urges, or ideas from conscious awareness	A person may experience loss of memory for unpleasant events.
Rationalization	Attempting to make actions or mistakes seem reasonable	The reasons or excuses given for behavior (e.g., "I spank my children because it is good for them") sound rational, but they may not be the real reasons.
Projection	Unconsciously attributing one's own unacceptable thoughts or impulses to another person	Instead of recognizing that "I hate him," a person may feel that "he hates me."
Reaction formation	Defending against unacceptable impulses by acting opposite to them	Sexual interest in a married coworker might appear as strong dislike instead.
Sublimation	Converting unacceptable impulses into socially acceptable actions and perhaps expressing them symbolically	Sexual or aggressive desires may appear as artistic creativity or devotion to athletic excellence.
Displacement	Deflecting an impulse from its original target to a less threatening one	Anger at one's boss may be expressed through hostility toward a clerk, a family member, or even a pet.
Denial	Simply discounting the existence of threatening impulses	A person may vehemently deny ever having had even the slightest degree of physical attraction to a person of the same sex.
Compensation	Striving to make up for unconscious impulses or fears	A business executive's extreme competitiveness might be aimed at compensating for unconscious feelings of inferiority.

preventing threatening material from surfacing or disguising it when it does appear (Cramer, 2009) (see Table 14.1).

Stages in Personality Development Freud proposed that personality evolves during childhood in several stages of **psychosexual development**. Failure to resolve the problems and conflicts that appear at a given stage can leave a person *fixated*—that is, unconsciously preoccupied with the area of pleasure associated with that stage. Freud believed that the stage at which a person became fixated in childhood can be seen in adult personality characteristics.

In Freud's theory, a child's first year or so is called the **oral stage** because the mouth—which infants use to eat and to explore everything from toys to their own hands and feet—is the center of pleasure during this period. Freud said fixation at the oral stage can stem from weaning that is too early or too late and may result in adult characteristics ranging from overeating or childlike dependence (late weaning) to the use of "biting" sarcasm (early weaning).

The **anal stage** occurs during the second year, when the child's ego develops to cope with parental demands for socially appropriate behavior. For example, in most Western cultures, toilet training clashes with the child's freedom to have bowel movements at will. Freud said that if toilet training is too harsh or begins too early, it can produce an anal fixation that leads, in adulthood, to stinginess or excessive neatness (symbolically withholding feces). If toilet training is too late or too lax, however, the result could be a kind of anal fixation that is reflected in adults who are disorganized or impulsive (symbolically expelling feces).

Big Cheese Photo RF/Jupiterimages

The Oral Stage

According to Freud, personality evolves in several stages of psychosexual development. At each stage, a different part of the body becomes the primary focus of pleasure. This baby would appear to be in the oral stage.

TRY THIS Which of Freud's ego defense mechanisms is operating here? (Check the answer at the bottom of page 562.)

DILBERT: © Scott Adams/Dist. by United Feature Syndicate, Inc.

According to Freud, between the ages of 3 and 5, the child's focus of pleasure shifts to the genital area. Because he emphasized male psychosexual development, Freud called this period the **phallic stage** (*phallus* is another word for *penis*). He believed that during this stage, a boy experiences sexual desire for his mother and a desire to eliminate, or even kill, his father, with whom the boy competes for the mother's affection. (Freud named this pattern of impulses the **Oedipal complex** because it reminded him of the plot of *Oedipus Rex,* the classical Greek play in which Oedipus, upon returning to his homeland, unknowingly slays his father and marries his mother.) The boy's fantasies make him fear that his powerful "rival" (his father) will castrate him. To reduce this fear, the boy's ego represses his incestuous desires and leads him to "identify" with his father and try to be like him. It is during this stage that the male's superego begins to develop.

According to Freud, a girl begins the phallic stage with a strong attachment to her mother. When she realizes that boys have penises and girls don't, though, she supposedly develops *penis envy* and transfers her love to her father. This pattern has become known as the **Electra complex** because it parallels the plot of another classical Greek play, but Freud himself never used this term. To avoid her mother's disapproval, the girl identifies with and imitates her, thus forming the basis for her own superego.

Freud believed that unresolved conflicts from the phallic stage can lead to many problems in adulthood, including difficulties in dealing with authority figures and an inability to maintain a stable love relationship.

As the phallic stage draws to a close and its conflicts are dealt with by the ego, an interval of psychological peace occurs. During this **latency period**, which lasts through childhood, sexual impulses stay in the background as the youngster focuses on education, same-sex peer play, and the development of social skills. In adolescence, when sexual impulses reappear at a conscious level, the genitals again become the focus of pleasure. Thus begins what Freud called the **genital stage**, which he saw as lasting for the rest of a person's life. The quality of relationships and the degree of fulfillment experienced during this final stage, he claimed, are influenced by how intrapsychic conflicts were resolved during the earlier stages.

Variations on Freud's Personality Theory

Freud's ideas—especially those involving the Oedipus and Electra complexes and the role of infantile sexuality—were, and still are, controversial. Even many of Freud's followers did not entirely agree with him. Some of them have been called *neo-Freudians* because they maintained many of the basic ideas in Freud's theory but developed their own approaches. Others are known as *ego psychologists* because their ideas focused more on the ego than on the id (Larsen & Buss, 2010).

Jung's Analytic Psychology Carl Jung (pronounced "yoong") was the most prominent of Freud's early followers to chart his own theoretical course. Jung (1916) emphasized that libido is not just sexual instinct but rather a more general life force

psychosexual development Periods of personality development in which, according to Freud, conflicts focus on particular issues.

oral stage The first of Freud's psychosexual stages of personality development, in which the mouth is the center of pleasure and conflict.

anal stage The second of Freud's psychosexual stages of personality development, in which the focus of pleasure and conflict shifts from the mouth to the anus.

phallic stage The third of Freud's psychosexual stages of personality development, in which the focus of pleasure and conflict shifts to the genital area.

Oedipal complex A pattern described by Freud in which a boy has sexual desire for his mother and wants to eliminate his father's competition for her attention.

Electra complex A pattern described by Freud in which a young girl develops an attachment to her father and competes with her mother for his attention.

latency period The fourth of Freud's psychosexual stages of personality development, in which sexual impulses lie dormant.

genital stage The last of Freud's psychosexual stages of personality development, which begins during adolescence, when sexual impulses appear at the conscious level.

that includes an innate drive for creativity, for growth-oriented resolution of conflicts, and for the productive adjustment of basic impulses in light of real-world demands. Jung did not identify specific stages in personality development. He suggested instead that people gradually develop differing degrees of *introversion* (a tendency to reflect on one's own experiences) or *extraversion* (a tendency to focus on the social world), along with differing tendencies to rely on specific psychological functions, such as thinking versus feeling. Combinations of these differing tendencies, said Jung (1933), create personalities that display distinctive and predictable patterns of behavior.

Jung also claimed there is a *collective unconscious,* which contains the memories we have inherited from our human and nonhuman ancestors (Freidman & Schustack, 2009). According to Jung, we are not consciously aware of these memories, but they are responsible for our innate tendencies to react in particular ways to certain things. For example, Jung believed that our collective memory of mothers influences how each of us perceives our own mother. Although the notion of a collective unconscious is widely accepted by Jung's followers, there is no empirical evidence that it exists. In fact, Jung himself acknowledged that to objectively demonstrate the existence of a collective unconscious would be impossible (Feist & Feist, 2009).

Other Neo-Freudian Theorists Jung was not the first theorist to challenge Freud. Alfred Adler, once a loyal follower of psychoanalysis, came to believe that the power behind the development of personality comes not from id impulses but from an innate desire to overcome infantile feelings of helplessness and to gain some control over the environment. Adler (1927/1963) referred to this process as *striving for superiority,* by which he meant a drive for fulfillment as a person, not just a desire to do better than others. Other prominent neo-Freudians, including Erik Erikson, Erich Fromm, and Harry Stack Sullivan, focused on how people's personalities are shaped by those around them. They argued that once our biological needs are met, the attempt to meet social needs (to feel protected, secure, and accepted, for example) is the primary influence on personality. And according to these theorists, the strategies people use to meet these social needs, such as by dominating others or being dependent on them, become central features of their personalities.

The first feminist personality theorist, Karen Horney (pronounced "HORN-eye"), disputed Freud's view that women's lack of a penis causes them to envy men and feel inferior to them. Horney (1937) argued that, in fact, it is men who envy women: Realizing that they cannot bear children and that they often play only a small role in raising them, males see their lives as having less meaning or substance than women's. Horney believed that it is this *womb envy* that leads men to belittle and disrespect women. She argued further that when women feel inferior, it is because of the personal and political restrictions that men have placed on them, not because of penis envy. Horney's position on this issue reflected her strong belief that cultural factors, rather than instincts, play a major role in personality development (Hergenhahn & Olson, 2007). This greater emphasis on cultural influences is one of the major theoretical differences between Freud and the neo-Freudians.

An Early Feminist

After completing medical school at the University of Berlin in 1913, Karen Horney (1885–1952) trained as a Freudian psychoanalyst. She accepted some aspects of Freud's views, including the idea of unconscious motivation, but she eventually developed her own neo-Freudian theory. She saw the need for security as more important than biological instincts in motivating infants' behavior. She also rejected Freud's notion that the psychological development of females is influenced by penis envy.

Contemporary Psychodynamic Theories

Some of the most influential psychodynamic approaches to personality now focus on *object relations*—that is, on how people's perceptions of themselves and others influence their view of, and reactions to, the world (Westen et al., 2008). Early object relations theorists including Melanie Klein (1991), Otto Kernberg

---

The defense mechanism illustrated in the cartoon on page 561 is displacement.

(1984), Heinz Kohut (1984), and Margaret Mahler (1968) regarded the first relationships between infants and their love objects—usually the mother and other primary caregivers—as vitally important in the development of personality (Klein, 1975; Kohut, 1984; Sohlberg & Jansson, 2002). In their view, these relationships shape a person's thoughts and feelings about social relationships later in life (Westen et al., 2008).

A close cousin of object relations theory is called *attachment theory* because it focuses specifically on the early attachment process. As described in the chapter on human development, the ideal attachment pattern occurs when infants form a secure early bond to their mothers or other caregivers, tolerate gradual separation from this "attachment object," and eventually develop the ability to relate to others as independent, secure individuals (Ainsworth & Bowlby, 1991). Some infants do not develop this *secure attachment,* though. Instead, they may display various kinds of *insecure attachments*. Attachment theorists have found evidence that the nature of people's early attachments is associated with differences in their self-image, identity, security, and social relationships in adolescence, adulthood, and even old age (Mattanah, Hancock, & Brand, 2004; Mikulincer & Shaver, in press; Simpson et al., 2007; Simpson, Rholes, & Winterheld, 2010). In one study, women who had been securely attached in childhood were more likely to have happy marriages than women whose childhood attachments had been insecure (Klohnen & Bera, 1998). In another study, people with insecure attachments were less likely than those with secure attachments to be helpful when they encountered a person in distress (Mikulincer & Shaver, 2005). Further evidence along these lines comes from a long-term study of children diagnosed with severe heart disease. The children whose mothers had not been securely attached to their own mothers tended to show greater evidence of anxiety and other emotional difficulties in the years following the diagnosis than those whose mothers had been more securely attached (Berant, Mikulincer, & Shaver, 2008). In short, attachment theorists suggest that people who miss the opportunity to become securely attached to their mothers or other adults may suffer significant disturbances in their later relationships (Aizawa, 2002), including those with their own children.

Evaluating the Psychodynamic Approach

Freud's personality theory is probably the most comprehensive and influential psychological theory ever proposed, and it has influenced modern Western thinking about medicine, literature, religion, sociology, and anthropology. It has also shaped a wide range of psychotherapy techniques and stimulated the development of several personality assessments, including the projective tests described later in this chapter. Some of Freud's ideas have received support from research on cognitive processes. For example, psychologists have found that people do employ several of the defense mechanisms Freud described (Cramer, 2007), although it is unclear whether these always operate at an unconscious level. As mentioned in the chapter on consciousness, there is also evidence that people's thoughts and actions can be influenced by unrecalled events and experiences (Bargh & Morsella, 2008; Dijksterhuis et al., 2008; Kihlstrom, 2008) and perhaps by emotions that are not consciously felt (Williams et al., 2009). Some researchers believe that unconscious processes may affect people's health (Goldenberg et al., 2008).

However, Freud's psychodynamic theories have several weaknesses. For one thing, they are based almost entirely on case studies of a few individuals. As discussed in the chapter on research in psychology, conclusions drawn from case studies may not apply to people in general. Nor was Freud's sample representative of people in general. Most of his patients were upper-class Viennese women who not only had psychological problems but also were raised in a culture in which discussion of sex was considered to be uncivilized. Moreover, Freud's thinking about personality reflected western European and North American values, which may or may not be helpful in understanding people in other cultures (Schultz & Schultz, 2009). For example, the concepts of ego and self that are so central to Freud's personality theory (and those of his followers) are based on the self-oriented values of individualist cultures. These values may be less central to personality development in the more collectivist cultures of, say, Asia and South America (Morling & Kitayama, 2008).

Freud's conclusions may have been distorted by other biases as well. Freudian scholars suggest, for example, that Freud may have modified reports of what happened during therapy so as to better fit his theory (Esterson, 2001; Schultz & Schultz, 2009). He may also have asked leading questions that influenced patients to "recall" events from childhood that never really happened (Esterson, 2001). Today, as noted in the chapter on memory, there are similar concerns that some patients who recover allegedly repressed memories about childhood sexual abuse by parents may actually be reporting false memories implanted by their therapists (Loftus, Garry & Hayne, 2008).

Freud's focus on male psychosexual development and his notion that females envy male anatomy have also caused feminists of both sexes to reject some or all of his ideas. In the tradition of Horney, some contemporary female neo-Freudians have proposed theories that focus specifically on the psychosexual development of women (Sayers, 1991).

Finally, judged by today's standards, Freud's theory is not very scientific. His definitions of id, ego, unconscious conflict, and other concepts lack the precision required for scientific measurement and testing (Carver & Scheier, 2008). His belief that human beings are driven mainly by unconscious desires ignores evidence that much human behavior goes beyond impulse gratification. The conscious drive to reach personal, social, and spiritual goals is also an important determinant of behavior, as is learning from others.

Some of the weaknesses in Freudian theory have been addressed by theorists who have altered some of Freud's concepts and devoted more attention to social influences on personality. Attempts have also been made to increase precision and objectivity in the measurement of psychodynamic concepts (e.g., Barber, Crits-Christoph, & Paul, 1993). Research on concepts from psychodynamic theory is, in fact, becoming more sophisticated and increasingly reflects interest in subjecting psychodynamic principles to empirical tests (e.g., Betan & Westen, 2009; Roffman & Gerber, 2008; Wegner, Wenzlaff, & Kozak, 2004). Still, the psychodynamic approach is better known for generating hypotheses about personality than for scientifically testing them. Accordingly, this approach to personality is now much less influential in mainstream psychology than it was in the past (Feist & Feist, 2009; Friedman & Schustack, 2009).

The Trait Approach

You could probably describe the personality of someone you know well with just a few statements. For example, you might say, "He is a caring person and a true extravert. He is generous with his time and conscientious about everything he does. Yet sometimes he is not very assertive or confident. He always gives in to other people's demands because he wants to be accepted by them."

In other words, most people describe others by referring to the kinds of people they are ("extravert," "conscientious"); to the thoughts, feelings, and actions that are most typical of them ("caring," "not very assertive," "generous"); or to their needs ("wants to be accepted"). Together these statements describe personality *traits*—the inclinations or tendencies that direct how a person usually thinks and behaves (Pervin, Cervone, & John, 2005).

The **trait approach** to personality makes three basic assumptions:

1. Personality traits are relatively stable and therefore predictable over time. So a gentle person tends to stay that way day after day, year after year (Cervone & Pervin, 2008).
2. Personality traits are relatively stable across situations, and they can explain why people act in predictable ways in many different situations. A person who is competitive at work will probably also be competitive in sports or at a party (Roberts, Woods, & Caspi, 2008).
3. People differ in how much of a particular personality trait they possess; no two people are exactly alike on all traits. The result is an endless variety of unique human personalities.

Traits Versus Types Theories about enduring differences in people's personality characteristics go back at least as far as Hippocrates, a physician of ancient Greece. He suggested that a certain temperament, or basic behavioral tendency, is associated with each of four bodily fluids, or humors: blood, phlegm, black bile, and yellow bile. Personality, said Hippocrates, depends on how much of each humor a person has. His terms for the four humor-based personalities—*sanguine* (optimistic), *phlegmatic* (slow, lethargic), *melancholic* (sad, depressive), and *choleric* (angry, irritable)—still survive today.

Notice that Hippocrates was describing personality *types,* not traits. Traits involve *quantitative* differences among people—such as how much of a certain characteristic they have. Types involve *qualitative* differences, such as whether someone possesses a certain characteristic at all. When people are "typed," they are said to belong to one class or another—such as male or female. Modern type theories of personality try to do the same by placing people in one category or another (Funder, 2007). For example, some researchers claim to have identified three qualitatively different basic personality types (Caspi, 1998; Hart, Atkins, & Fegley, 2003; van Leeuwen, de Fruyt, & Mervielde, 2004): the *well-adjusted,* or *resilient, person*, who is flexible, resourceful, and successful with other people; the *maladjusted overcontrolling person,* who is too self-controlled to enjoy life and is difficult for others to deal with; and the *maladjusted undercontrolling person,* whose excessive impulsiveness can be dangerous both for the

APPLYING PSYCHOLOGY Some psychologists employ type and trait theories of personality as they advise prosecution or defense attorneys about which potential jurors are most likely to be sympathetic to their side in a court case.

trait approach The view that personality is a combination of characteristics that people display over time and across situations.

person and for others. (This chapter's Focus on Research Methods section contains more information on these and other types.)

Type theories have recently gained acceptance among some personality researchers, but the majority of researchers doubt that it's possible to compress the dazzling range of human characteristics into a just few discrete types (McRae & Costa, 2006). Accordingly, the trait approach to personality remains much more influential. Trait theorists are interested in measuring the relative strength of the many personality characteristics that they believe are present in everyone (see Figure 14.2). Most of today's trait theories of personality have their origins in the work of Gordon Allport, Raymond Cattell, and Hans Eysenck.

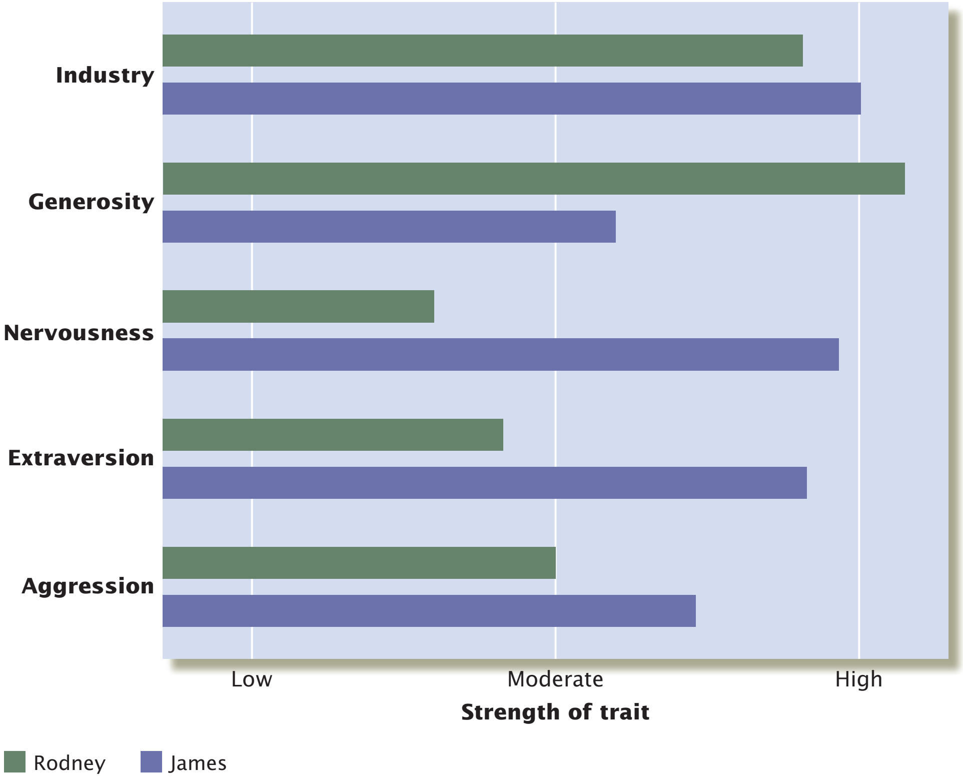
Allport's Trait Theory

Gordon Allport spent thirty years searching for the traits that combine to form personality. He found nearly eighteen thousand dictionary terms that can be used to describe human behavior (Allport & Odbert, 1936; John, Naumann, & Soto, 2008), but he noticed that many of these terms referred to the same thing (e.g., *hostile*, *nasty*, and *mean* all convey a similar meaning). So if you were to jot down the personality traits that describe a close friend or relative, you would probably be able to capture that individual's personality using only about seven trait labels. Allport believed that the set of labels chosen to describe a particular person reflects that person's *central traits*—characteristics that are usually obvious to others and that organize and control behavior in many different situations. Central traits are roughly equivalent to the descriptive terms used in letters of recommendation (*reliable* or *distractible*, for example) that are meant to convey what can be expected from a person most of the time (Schultz & Schultz, 2009). Allport also believed that people possess *secondary traits*—characteristics that are more specific to certain situations and control far less behavior. "Dislikes crowds" is an example of a secondary trait.

FIGURE 14.2

Two Personality Profiles

TRY THIS Trait theory describes personality in terms of the strength of particular dimensions, or traits. Here are trait profiles for Rodney, a social worker, and James, a sales clerk. Compared with James, Rodney is about equally industrious, more generous, and less nervous, extraverted, and aggressive. Just for fun, mark this figure to indicate how strong you think you are on each of the listed traits. Trait theorists suggest that this should be easy for you to do because, they say, virtually everyone displays a certain amount of almost any personality characteristic.



Allport's research helped lay the foundation for modern research on personality traits. And though his emphasis on the uniqueness of each individual personality made it difficult to draw conclusions about the structure of human personality in general (Barenbaum & Winter, 2008), some researchers today continue to employ a modern version of Allport's approach (e.g., Caldwell, Cervone, & Rubin, 2008).

The Five-Factor Personality Model

In recent years, trait approaches have continued to focus on identifying and describing a core structure of personality that appears in everyone. This work owes much to Allport and also to a British psychologist named Raymond Cattell (pronounced "kuh-TEL"). Cattell asked people to rate themselves and others on many of the trait-descriptive terms that Allport had identified. He then used a mathematical technique called *factor analysis* to study which of these terms were related to one another. Factor analysis can reveal, for example, whether someone who is moody is also likely to be anxious, rigid, and unsociable. Cattell believed that the sets of traits clustering together in this analysis would reflect a set of basic personality *factors* or dimensions. His analyses eventually identified sixteen such factors, including shy versus bold, trusting versus suspicious, and relaxed versus tense. Cattell believed that these factors can be found in everyone, and he measured their strength using a test called the Sixteen Personality Factor Questionnaire, or 16PF (Cattell, Eber, & Tatsuoka, 1970).

More recent factor analyses by researchers such as Paul Costa and Robert McCrae (2008) have led many trait theorists to believe that personality is organized around only five basic factors. The components of this **five-factor personality model** (also known as the **Big Five model**) are *openness to experience, conscientiousness, extraversion, agreeableness,* and *neuroticism* (see Table 14.2). The importance of the five-factor model is suggested by the fact that different investigators find these factors (or a set very similar to them) when they factor-analyze data from personality inventories, peer ratings of personality characteristics, checklists of descriptive adjectives, and many other sources (John, Naumann, & Soto, 2008; McCrae & Costa, 2008). The fact that some version of the Big Five factors reliably appears in many countries and cultures—including Canada, China, the Czech Republic, Germany, Greece, Finland, India, Japan, Korea, the Philippines, Poland, Turkey, and Zimbabwe (Ashton et al., 2004; Heine & Buchtel, 2009; McCrae & Costa, 2006; Yamagata et al., 2006)—provides further evidence that these few dimensions may represent the most important components of human personality (McCrae, Terracciano, & Personality Profiles of Cultures Project, 2005).

TABLE 14.2 Dimensions of the Five-Factor Personality Model

Here is a list of the adjectives that define the Big Five personality factors. It will be easier to remember these factors if you notice that the first letters of their names spell the word *ocean.*

Dimension	Defining Descriptors
Openness to experience	Artistic, curious, imaginative, insightful, original; having wide interests, unusual thought processes, intellectual interests
Conscientiousness	Efficient, organized, planful, reliable, thorough, dependable, ethical, productive
Extraversion	Active, assertive, energetic, outgoing, talkative, gesturally expressive, gregarious
Agreeableness	Appreciative, forgiving, generous, kind, trusting, noncritical, warm, compassionate, considerate, straightforward
Neuroticism	Anxious, self-pitying, tense, emotionally unstable, impulsive, vulnerable, touchy, worrying

Animal Personalities

The idea that personality can be described in terms of five main dimensions seems to hold for some animals as well as humans. The five animal dimensions vary from human traits but are related to them. For example, hyenas differ from one another in terms of dominance, excitability, agreeableness (toward people), sociability (toward each other), and curiosity. Some of these same traits have been observed in a wide variety of other species, including sheep, langurs, orangutans, chipmunks, chimpanzees, and even fish (Bell & Sih, 2007; Gosling, 2001; King, Weiss, & Farmer, 2005; Konecná et al., 2008; Martin & Réale, 2008; Michelana et al., 2009; Weiss, King, & Perkins, 2006). Dog and cat lovers often report such traits in their pets, too (Gosling, Kwan, & John, 2003; Lee, Ryan, & Kreiner, 2007; Ley, Bennett, & Coleman, 2009).

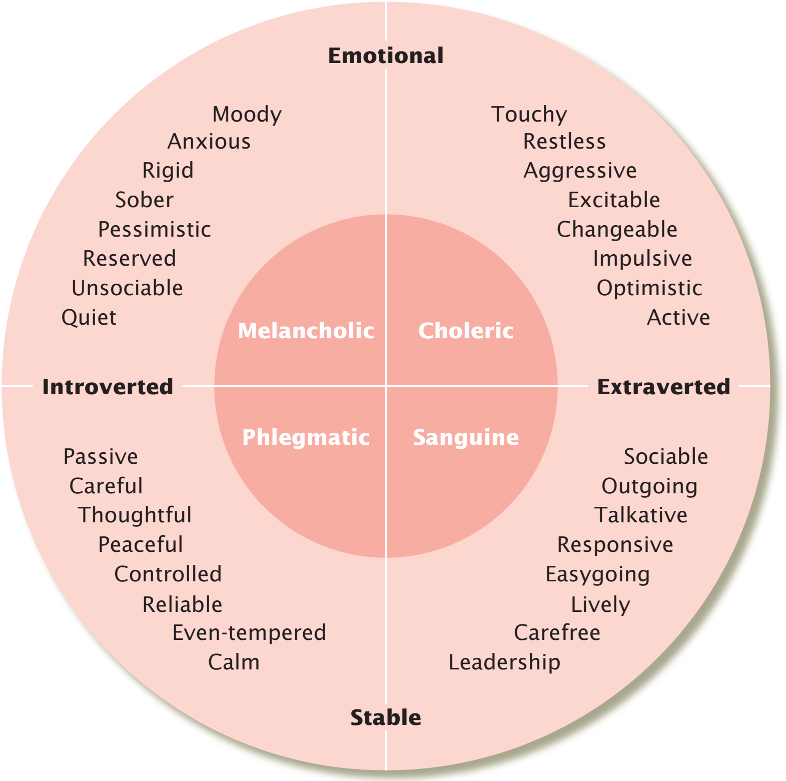
Many trait theorists believe that the five-factor model represents a major breakthrough in examining the personalities of people who come from different backgrounds, differ in age, and live in different parts of the world (John, Naumann, & Soto, 2008). It has certainly enabled psychologists to provide a comprehensive description of the basic similarities and differences in people's personalities and to explore how these factors are related to everything from attachment styles, social skills, and personality disorders to happiness, academic performance, physical well-being, and even future weight gain (e.g., Brummett et al., 2006; Cuperman & Ickes, 2009; Diener, 2000; Lynam & Widiger, 2001; Noftle & Shaver, 2006; Poropat, 2009; Roberts et al., 2009).

Biological Trait Theories

Some personality theorists are interested not only in what traits form the core of human personality but also in why people differ on these traits. Their research suggests that trait differences reflect the operation of some important biological factors (DeYoung et al., 2010; Terracciano et al., 2010).

Eysenck's Biological Trait Theory Like Cattell, the British psychologist Hans Eysenck (pronounced "EYE-sink") used factor analysis to study the structure of personality and thus helped lay the groundwork for the five-factor personality model. Eysenck suggested that most people's traits could be described using two main dimensions—*introversion-extraversion* and *emotionality-stability* (Eysenck 1990a, 1990b; see Figure 14.3):

1. *Introversion–extraversion.* Extraverts are sociable and outgoing, enjoy parties and other group activities, take risks, and love excitement and change. Introverts tend to be quiet, thoughtful, and reserved, enjoying solitary pursuits and avoiding excitement and social involvement.
2. *Emotionality–stability.* At one extreme of the emotionality–stability dimension are people who display such characteristics as moodiness, restlessness, worry, anxiety, and other negative emotions. Those at the opposite extreme are calm, even-tempered, relaxed, and emotionally stable. (This dimension is also often called *neuroticism.*)



Emotional
Moody
Anxious

Stable

FIGURE 14.3

Eysenck's Main Personality Dimensions

TRY THIS According to Eysenck, varying degrees of emotionality–stability and introversion–extraversion combine to produce predictable trait patterns. Notice that an introverted but stable person is likely to be controlled and reliable, whereas an introverted emotional person is likely to be rigid and anxious. (The traits appearing in the quadrants created by crossing these two personality dimensions correspond roughly to Hippocrates' four temperaments.) Which section of the figure do you think best describes your personality traits? How about those of a friend or a relative? Did you find it any easier to place other people's personalities in a particular section than it was to place your own personality? If so, why do you think that might be?

Source: Eysenck, H.J., Rachman, S. *The Causes and Cures of Neurosis: An Introduction to Modern Behavior Therapy Based on Learning Theory and the Principle of Conditioning*. Copyright © 1965. Edits. Reprinted with permission.

Eysenck argued that the variations in personality characteristics that we see among individuals can be traced to inherited differences in their nervous systems, especially in their brains. These biological differences, he said, create variations in people's typical levels of physiological arousal and in their sensitivity to stress and other environmental stimulation. For example, as mentioned in the motivation and emotion chapter, people who inherit a nervous system that normally operates below their optimum arousal level will always be on the lookout for excitement, change, and social contact in order to increase their arousal. As a result, these people will be *extraverted*. In contrast, people whose nervous system is normally "overaroused" will tend to avoid excitement, change, and social contact in order to reduce arousal to their optimum level. In short, they will be *introverted*. What about the emotionality–stability dimension? Eysenck said that people who score toward the stability side have nervous systems that are relatively insensitive to stress; those who are more emotional have nervous systems that react more strongly to stress.

Gray's Reinforcement Sensitivity Theory Jeffrey Gray, another British psychologist, agrees with Eysenck about the two basic dimensions of personality, but he offers a different explanation of the biological factors underlying them (Corr, 2002; DeYoung et al., 2010; Gray & McNaughton, 2000). According to Gray's *reinforcement sensitivity theory,* differences among people in introversion–extraversion and emotionality–stability originate in brain regions containing systems that influence how sensitive people are to different kinds of events: the behavioral approach system and the flight or freeze system (Pickering & Gray, 1999). The *behavioral approach system,* or *BAS,* affects people's sensitivity to rewards and their motivation to seek those rewards. The BAS has been called a "go" system because it is responsible for how impulsive or uninhibited a person is. The *flight or freeze system,* or *FSS,* affects how sensitive people are to potential punishment and the motivation to avoid being punished (Smillie, Pickering, & Jackson, 2006). The FSS is a "stop" system that is responsible for how fearful or inhibited a person is (Bijttebier et al., 2009).

In explaining Eysenck's personality dimensions, Gray sees extraverts as having a sensitive reward system (BAS) and an insensitive punishment system (FSS). Introverts are just the opposite—they are relatively insensitive to rewards but highly sensitive to punishment. Similarly, emotionally unstable people are much more sensitive to both rewards and punishments than those who are emotionally stable.

Gray's theory has its critics (e.g., Jackson, 2003; Matthews, 2008), but it is now more widely accepted than Eysenck's theory—primarily because it is being supported by other research (e.g., Revelle, 2008) and because it is more consistent with what neuroscientists know about brain structures, neurotransmitters, and how they operate (Buckholtz et al., 2008; Joseph et al., 2009; Read et al., 2010; Reuter et al., 2006).

THINKING **CRITICALLY**

Are Personality Traits Inherited?

Gray's reinforcement sensitivity theory is one of several new biologically oriented explanations of the origins of personality traits (e.g., Depue, 2007). A related approach involves investigating the genetics of these traits (e.g., Joyce et al., 2009; Terracciano et al., 2010). Consider the case of identical twins who were separated at 5 weeks of age and did not meet again for thirty-nine years. Both men drove Chevrolets, chain-smoked the same brand of cigarettes, had been divorced from women named Linda, had remarried women named Betty, had sons named James Allan, had dogs named Toy, enjoyed similar hobbies, and had served as sheriff's deputies (Tellegen et al., 1988).

What am I being asked to believe or accept?

Case studies like these have helped focus the attention of behavioral geneticists on the possibility that some core aspects of personality may be partly, or even largely, inherited (Johnson et al., 2009; Kreuger & Johnson, 2008; Yamagata et al. 2006).

What evidence is available to support the assertion?

The evidence and the arguments regarding this assertion are much like those presented in the chapter on cognitive abilities, in which we discuss the origins of differences in intelligence. Stories about children who seem to have their parents' or grandparents' bad temper, generosity, or shyness are often presented in support of the heritability of personality. And in fact, family resemblances in personality do provide an important source of evidence. Several studies have found moderate but significant correlations between children's personality test scores and those of their parents and siblings (Davis, Luce, & Kraus, 1994; DeYoung, Quilty, & Peterson, 2007; Loehlin et al., 1998).

Even stronger evidence comes from studies conducted around the world comparing identical twins raised together, identical twins raised apart, nonidentical twins raised together, and nonidentical twins raised apart (Larsen & Buss, 2010). Whether they are raised apart or together, identical twins (who have exactly the same genes) tend to be more alike in personality than nonidentical twins (whose genes are no more similar than those of other siblings). This research also shows that identical twins are more alike than nonidentical twins in general temperament, such as how active, sociable, anxious, and emotional they are, their positive attributes, and where they fall on the Big Five personality dimensions (e.g., Borkenau et al., 2006; Johnson et al., 2009). On the basis of such twin studies, behavioral geneticists have concluded that about 50 percent of the differences among people in terms of personality traits are due to genetic factors (Kreuger et al., 2008).

Are there alternative ways of interpreting the evidence?

Family resemblances in personality could reflect genetic or social influence. So an obvious alternative interpretation of this evidence might be that family similarities come not from common genes but from a common environment, especially from the examples set by parents and siblings. Children learn many rules, skills, and actions by

Family Resemblance
Do children inherit personality traits in the same direct way as they inherit facial features, coloration, and other physical characteristics? Research in behavioral genetics suggests that personality is the joint product of genetically influenced behavioral tendencies and the environmental conditions each child encounters.

© Rosanne Olson/Taxi/Getty Images

watching the people around them; perhaps children learn their personalities as well (Funder, 2007). The fact that siblings who aren't twins are less alike than twins may well result from what are called *nonshared environments* (Plomin, 2004). A child's place in the family birth order, differences in the way parents treat each of their children, and accidents and illnesses that alter a particular child's life or health are examples of nonshared factors that can have a differential impact on each individual (Loehlin, Neiderhiser, & Reiss, 2003). Nontwins are more likely than twins, especially identical twins, to be affected by nonshared environmental factors.

What additional evidence would help evaluate the alternatives?

One way to evaluate the idea that personality is inherited would be to locate genes that are associated with certain personality characteristics (Ebstein, 2006). Genetic differences have already been tentatively associated with certain behavior disorders, but most behavioral genetics researchers doubt that there are direct links between specific genes and particular personality traits (Kreuger & Johnson, 2008; Caspi, Roberts, & Shiner, 2005).

Another way to evaluate the role of genes in personality is to study people in infancy, before the environment has had a chance to exert its influence. If the environment were entirely responsible for personality, all newborns should be essentially alike. However, as discussed in the chapter on human development, they show immediate differences in *temperament*—varying markedly in activity, sensitivity to the environment, tendency to cry, and interest in new stimuli (Rothbart & Derryberry, 2002). These differences suggest biological and perhaps genetic influences.

To evaluate the relative contributions of nature and nurture beyond infancy, psychologists have examined the characteristics of adopted children. If adopted children are more like their biological parents than their adoptive parents, this suggests the influence of heredity in personality. If they are more like their adoptive families, a strong role for environmental factors in personality would be suggested. In actuality, adopted children's personalities tend to resemble the personalities of their biological parents and siblings more than those of the families in which they are raised (Kreuger & Johnson, 2008).

Further research is needed to determine more clearly what aspects of the environment are most important in shaping personality. So far, the evidence suggests that elements in the shared environment that affect all children in the family to varying degrees (socioeconomic status, for example) are probably not the main reason that identical twins show similar personalities. As mentioned earlier, however, nonshared environmental influences may be very important in personality development (Kendler & Neale, 2009). In fact, some researchers believe that nonshared influences must be considered even when trying to explain the greater similarities between identical twins reared apart than among nontwin siblings reared together. Additional research on the role of nonshared factors in personality development and the ways in which these factors might differentially affect twin and nontwin siblings' development is obviously vital. It will also be important to investigate the ways in which the personalities of individual children may affect the nature of the environment in which they are raised (Krueger, Markon, & Bouchard, 2003; see also the behavioral genetics appendix).

What conclusions are most reasonable?

Even researchers who support genetic theories of personality caution that we should not replace "simpleminded environmentalism" with the equally incorrect view that personality is almost completely biologically determined (Plomin & Crabbe, 2000). As with cognitive abilities, it is pointless to talk about heredity *versus* environment as causes of personality because nature and nurture always intertwine to exert joint and simultaneous influences. For example, we know that genetic factors affect the environment in which people live (e.g., their families) and how they react to their environment, but research in *epigenetics* has shown that environmental factors can influence which of a person's genes are activated (or "expressed") and how much those genes affect the person's behavior (see the chapter on research in psychology; Champagne & Mashoodh, 2009; Kreuger & Johnson, 2008).

With these findings in mind, it is best to draw rather tentative conclusions about the sources of differences in people's personalities. The evidence available so far suggests that genetic influences do appear to contribute significantly to personality differences. However, it is important to understand the implications of this statement. There is still no evidence that there is any single gene for any specific personality trait (Kreuger & Johnson, 2008). The genetic contribution to personality most likely comes through the influence of *sets* of genes that shape people's nervous systems and thus influence their general predispositions toward certain temperaments (Arbelle et al., 2003; Ebstein, 2006; Grigorenko, 2002). Temperamental factors—such as how active, emotional, and sociable a person is—then combine with environmental factors, such as a person's interactions with other people, to produce specific features of personality (Caspi, Roberts, & Shiner, 2005). For example, children who inherit a tendency toward emotionality might play less with other children, withdraw from social interactions, and thereby fail to learn important social skills (Spinrad et al, 2006). These experiences and tendencies, in turn, might lead to the self-consciousness and shyness seen in introverted personalities. Genes also appear to influence people's emotional responses to specific events, such as having a child or being socially rejected (Dornbos et al., 2009; Way, Taylor, & Eisenberger, 2009).

Notice, though, that genetic predispositions toward particular personality characteristics may or may not appear in behavior, depending on whether the environment supports or suppresses them. Changes in genetically influenced traits are not only possible but may actually be quite common as children grow (Cacioppo et al., 2000). So even though there is a strong genetic basis for shyness, many children learn to overcome this tendency and become rather outgoing (Leary, 2001). In summary, it appears that rather than inheriting specific traits, people inherit the raw materials out of which personality is shaped by the world.

Evaluating the Trait Approach

The trait approach, especially the five-factor personality model, has gained such wide acceptance that it tends to dominate contemporary research into personality. Yet there are several problems and weaknesses associated with this approach.

For one thing, trait theories seem better at describing people than at understanding them. It is easy to say, for example, that Marilyn is nasty to others because she has a strong hostility trait; but other factors, such as the way people treat her, could also be responsible. Indeed, trait theories have typically focused more on *how* people behave than on *why* they act as they do (Mischel, 2004a, 2004b). Nor do trait theories say much about how traits are related to the thoughts and feelings that precede, accompany, and follow behavior. Do introverts and extraverts decide to act as they do, can they behave otherwise, and how do they feel about their actions and experiences? Some personality psychologists are now linking their research to that of cognitive psychologists in an effort to better understand how thoughts and emotions influence, and are influenced by, personality traits (e.g., Shoda & LeeTiernan, 2002). And as suggested in the Thinking Critically discussion, other psychologists have become interested in the role of genes, brain structures, and neurotransmitters as causes of the individual differences we see among people's personality traits (e.g., Canli, 2008; Netter, 2006).

Still, the trait approach has been faulted for offering a short list of traits that provides, at best, a fixed and superficial description of personality that fails to capture how traits combine to form a complex and dynamic individual (Block, 2001; Funder, 2007). Also, some people have questioned whether there are exactly five core dimensions of personality. Some research suggests, for example, that there might be a sixth dimension, involving honesty and humility (Lee, Ogunfowora, & Ashton, 2005). Others have questioned whether the factors are exactly the same in all cultures (De Raad et al., 2010; Heine & Buchtel, 2009). But even if the five-factor model is correct and universal, its factors are not all-powerful because situations also affect behavior. For example, people high in extraversion are not always sociable. Whether they behave sociably depends in part on where they are and who else is present.

In fairness, early trait theorists such as Allport did implicitly acknowledge the importance of situations in influencing behavior, but it is only recently that consideration of person-situation interactions has become an explicit part of trait-based approaches to personality. This change is largely the result of research conducted by psychologists who have taken a social-cognitive approach to personality, which we describe next.

The Social-Cognitive Approach

The **social-cognitive approach** to personality differs from the psychodynamic and trait approaches in two important ways. First, social-cognitive theorists look to *conscious* thoughts and emotions for clues to how people differ from one another and what guides their behavior (Mischel & Shoda, 2008). Second, the social-cognitive approach did not grow out of clinical cases or other descriptions of people's personalities. It was based instead on the principles of animal and human learning described in the chapter on learning. In fact, the founders of the social-cognitive approach were originally known as *social-learning theorists* because of their view that what we call "personality" consists mainly of the thoughts and actions we learn through observing and interacting with family and others in social situations (Bandura & Walters, 1963; Cervone & Pervin, 2008).

Roots of the Social-Cognitive Approach

Elements of the social-cognitive approach can be traced back to the behaviorism of John B. Watson. As described in the chapter on introducing psychology, Watson (1925) used research on classical conditioning to support his claim that all human behavior is determined by learning. B. F. Skinner broadened the behavioral approach by emphasizing the importance of operant conditioning in learning. Through what he called **functional analysis**, Skinner tried to understand behavior in terms of the

social-cognitive approach The view that personality reflects learned patterns of thinking and behavior.

functional analysis Analyzing behavior by studying what responses occur under what conditions of operant reward and punishment.

function it serves in obtaining rewards or avoiding punishment. For example, if observations show that a schoolboy's aggressive behavior occurs mainly when a certain teacher is present, it may be that aggression is tolerated by that teacher and may even be rewarded with special attention. Rather than describing personality traits, then, functional analysis summarizes what people find rewarding, what they are capable of doing, and what skills they lack.

The principles of classical and operant conditioning launched social-learning explanations of personality, but because they were focused on observable behavior, they were of limited usefulness to researchers who wanted to explore the role of thoughts in guiding behavior. As the social-learning approach evolved into the social-cognitive approach, it incorporated learning principles but also went beyond them.

Today, proponents of this very popular approach to personality seek to assess and understand how learned patterns of thoughts and feelings contribute to behavior and how behavior and its consequences alter cognitive activity, as well as future actions. In dealing with that aggressive schoolboy, for example, social-cognitive theorists would want to know not only what he has learned to do in certain situations (and how he learned it) but also what he thinks about himself, his teachers, and his behavior—and his expectations about each (Shoda & Mischel, 2006).

Prominent Social-Cognitive Theories

Julian Rotter, Albert Bandura, and Walter Mischel have presented the most influential social-cognitive personality theories.

Rotter's Expectancy Theory Julian Rotter (1982) argued that learning creates cognitions, known as *expectancies,* that guide behavior. Specifically, he said that a person's decision to engage in a behavior is determined by what the person expects to happen following the behavior and the value the person places on the outcome. For example, people spend lots of money on new clothes to be worn at job interviews, first because they have learned to expect that doing so will help get them the job and also because they place a high value on having the job. To Rotter, then, behavior is determined not only by the kinds of consequences that Skinner called *positive reinforcers* but also by the expectation that a particular behavior will result in those consequences (Mischel, 2004b).

Rotter himself focused mainly on how expectations shape particular behaviors in particular situations, but several of the researchers he influenced also examined people's more general expectations about what controls life's rewards and punishments. Those researchers noticed that some people (whom they called *internals*) are inclined to expect events to be controlled by their own efforts. These individuals assume that what they achieve and the reinforcements they receive are due to efforts they make themselves. Others (*externals*) are more inclined to expect events to be determined by external forces over which they have no control. When externals succeed, they are likely to believe that their success was due to chance or luck.

Research on differences in generalized expectancies does show that they are correlated with differences in behavior. For example, when threatened by a hurricane or other natural disaster, internals—in accordance with their belief that they can control what happens to them—are more likely than externals to buy bottled water and make other preparations (Sattler, Kaiser, & Hittner, 2000). When confronted with a personal problem, internals are more likely than externals to work to solve this problem. Externals are more likely to regard it as unsolvable (Gianakos, 2002). Internals also tend to work harder than externals at staying physically healthy and as a result may be healthier than externals (Stürmer, Hasselbach, & Amelang, 2006). We know, for example, that children with an internal control orientation are less likely than externals to become obese in later life (Gale, Batty, & Deary, 2008). Internals also tend to be more careful with money (Lim, Teo, & Loo, 2003). As college students, internals tend to be better informed about the courses they take, including what they need to do to

FIGURE 14.4

Reciprocal Determinism

Albert Bandura's notion of reciprocal determinism suggests that personal factors (such as cognitions, or thoughts), behavior, and the environment are constantly affecting one another. For example, a person's hostile thoughts may lead to hostile behavior, which gives rise to even more hostile thoughts. At the same time, the hostile behavior offends other people, which creates a threatening environment that causes the person to think and act in even more negative ways. As increasingly negative thoughts alter the person's perceptions of the environment, that environment seems to be more threatening than ever (Bushman et al., 2005).

get a high grade. Perhaps as a result, internals tend to get better grades and to graduate sooner than externals (Dollinger, 2000; Hall, Smith, & Chia, 2008).

Bandura and Reciprocal Determinism In his social-cognitive theory, Albert Bandura (1999, 2006) sees personality as shaped by the ways in which thoughts, behavior, and the environment influence one another. He points out that regardless of whether people learn through direct experience with rewards and punishments or through the observational learning processes described in the chapter on learning, their behavior causes changes in their environment. Observing these changes in turn affects how they think, which then affects their behavior, and so on in a constant web of mutual influence that Bandura calls *reciprocal determinism* (see Figure 14.4).

According to Bandura, an especially important cognitive element in this web of influence is perceived **self-efficacy**—the learned expectation of success. Bandura says that what we do, and what we try to do, is largely controlled by our perceptions or beliefs about our chances of success at a particular task or problem. The higher our perceived self-efficacy in relation to a particular situation or task, the greater our actual accomplishments in that situation or task (Greven et al., 2009; Zimmerman & Schunk, 2003). So going into a job interview with the belief that you have the skills necessary to be hired may lead to behaviors that help you get the job.

Expectancies about succeeding at a specific task can interact with expectancies about the consequences of behavior in general, thus helping shape the person's psychological well-being (Maddux & Gosselin, 2003). For example, if a person has low perceived self-efficacy about getting a better job and also expects that nothing anyone does has much effect on the world, the result may be apathy. But if a person with low perceived self-efficacy about a new job also believes that other people are enjoying the benefits of their efforts, the result may be self-criticism and depression.

Mischel's Cognitive-Affective Theory Social-cognitive theorists argue that learned beliefs, feelings, and expectancies characterize each individual and make that individual different from other people. Walter Mischel calls these characteristics *cognitive person variables,* and he believes that they outline the dimensions along which individuals differ (Mischel, 2009).

According to Mischel, the most important cognitive person variables are *encodings* (beliefs about the world and other people), *expectancies* (including self-efficacy and what can be expected following various actions), *affects* (feelings and emotions), *goals and values* (what a person believes in and wants to achieve), and *competencies and self-regulatory plans* (the things a person can do and the ability to thoughtfully plan and control goal-directed behavior) (Shoda & Mischel, 2006).

To predict a person's behavior in a particular situation, says Mischel, we need to know about these cognitive person variables, as well as about the features of the situation the person will face. In short, the person and the situation interact to produce behavior. Mischel's view has been called an "if-then" theory because he proposes that *if* people encounter a particular situation, *then* they will engage in the characteristic behaviors (called *behavioral signatures*) they have learned to display in that situation (Kammrath, Mendoza-Denton, & Mischel, 2005).

Mischel was once highly critical of trait theories of personality but now regards his own theory as generally consistent with that approach. In fact, the concept of behavioral signatures is quite similar to the concept of traits. However, Mischel still argues that trait theorists underestimate the power of situations to alter behavior and do not pay enough attention to the cognitive and emotional processes that underlie people's overt actions. Despite their remaining differences, most advocates of the trait and social-cognitive approaches are now focusing on the similarities between their views (Cervone, 2005; Funder, 2008). This trend toward reconciliation has clarified somewhat the relationship between personal and situational variables and how they

self-efficacy According to Albert Bandura, learned expectations about the probability of success in given situations.

The Impact of Situations

Arnold Schwarzenegger's behavior as an actor in the *Terminator* movies differed greatly from his behavior as the governor of California. Mischel's theory of personality emphasizes that person-situation interactions are vitally important in determining the behavior of everyone in a given environment.

affect behavior under various conditions. Many of the conclusions that have emerged are consistent with Bandura's concept of reciprocal determinism:

1. Personal dispositions (which include traits and cognitive person variables) influence behavior only in relevant situations. The trait of anxiousness, for example, may predict anxiety, but only in situations in which an anxious person feels threatened.
2. Personal dispositions can lead to behaviors that alter situations, and those altered situations in turn promote other behaviors. For example, a hostile child can trigger aggression in others and thus start a fight.
3. People choose to be in situations that are in tune with their personal dispositions. Introverts, for instance, are likely to choose quiet environments, whereas extraverts tend to seek out livelier, more social ones (Beck & Clark, 2009).
4. Personal dispositions are more important in some situations than in others. Under circumstances in which many different behaviors would all be appropriate—a company picnic, for example—what people do may be predicted from their dispositions (extraverts will probably play games and socialize while introverts watch). However, in situations such as a funeral, in which fewer options are socially acceptable, personal dispositions will not differentiate one person from another; everyone is likely to be quiet and somber.

Today, social-cognitive theorists devote much of their research to examining how cognitive person variables develop, how they are related to stress and health, and how they interact with situational variables to affect behavior.

Evaluating the Social-Cognitive Approach

The original behavioral view of personality appealed to many people. It offered an objective, experimentally oriented approach that operationally defined its concepts, relied on empirical data for its basic principles, and based its applications on the results of empirical research (Pervin, Cervone, & John, 2005). However, its successor, the social-cognitive approach, has gained even wider acceptance because it blends theories from behavioral and cognitive psychology and applies them to such socially important areas as aggression, the effects of mass media on children, and the development of self-regulatory processes that enhance personal control over behavior. The popularity of this approach also stems from the ease with which its principles can be translated into treatment procedures for many types of psychological disorders (O'Donohue, Fisher, & Hayes, 2003; see the chapter on treatment of psychological disorders).

Still, the social-cognitive approach has not escaped criticism. Psychodynamic theorists point out that social-cognitive theories leave no role for unconscious thoughts and feelings in determining behaviors (e.g., Westen et al., 2008). Some advocates of trait theory complain that social-cognitive theorists have focused more on explaining why traits are unimportant than on why situations are important and that they have failed to identify what it is about specific situations that brings out certain behaviors (Funder, 2008). The social-cognitive approach has also been faulted for failing to present a general theory of personality, offering instead a set of more limited theories that share certain common assumptions about the nature of personality (Feist & Feist, 2009). Most generally, the social-cognitive approach is considered incapable of capturing the complexity, richness, and uniqueness that some critics see as inherent in human personality (Carver & Scheier, 2008). According to these critics, a far more attractive alternative is provided by the humanistic psychology approach to personality.

The Humanistic Psychology Approach

humanistic psychology approach The view that personality develops through an actualizing tendency that unfolds in accordance with each person's unique perceptions of the world.

Unlike theories that emphasize the instincts and learning processes that humans seem to share with other animals, the **humanistic psychology approach** to personality focuses on mental capabilities that set humans apart: self-awareness, creativity, planning, decision making, and responsibility. Theorists who adopt the humanistic approach see human behavior as motivated mainly by an innate drive toward growth that prompts people to fulfill their unique potential. And like the planted seed whose natural potential is to become a flower, people are seen as naturally inclined toward goodness, creativity, love, and joy. Humanistic psychologists also believe that to explain people's actions in any particular situation, it is more important to understand their view of the world than their instincts, traits, or learning experiences. To humanists,

What Is Reality?

Each of these people has a different perception of what happened during the play that started this argument—and each is sure he is right! Disagreement about the "same" event illustrates *phenomenology*, each person's unique perceptions of the world. The humanistic psychology approach holds that these perceptions shape personality and guide behavior. As described in the perception chapter, our perceptions are often influenced by top-down processing. In this case, expectations and motivation stemming from differing loyalties are likely to influence reality—and reactions—for each team's players, coaches, and fans.

that worldview is a bit different for each of us, and it is this unique *phenomenology* (pronounced “fuh-nahm-uh-NAHL-uh-jee”), or way of perceiving and interpreting the world, that shapes personality and guides behavior (Kelly, 1980). From this perspective, then, no one can understand another person without somehow perceiving the world through that person’s eyes. All behavior, even seemingly weird behavior, is presumed to be meaningful to the person displaying it. Because it emphasizes the importance of looking at people’s perceptions, this approach is sometimes called the *phenomenological approach.*

The humanistic psychology approach to personality has many roots. The idea that each person perceives a different reality reflects the views of existential philosophers such as Søren Kierkegaard and Jean-Paul Sartre. The idea that people actively shape their own reality stems in part from the Gestalt psychologists, whose work is described in the chapter on perception, and from George Kelly, a psychologist who also influenced social-cognitive theorists. We can also hear echoes of Alfred Adler, Erich Fromm, and other psychodynamic theorists who emphasized the positive aspects of human nature and the importance of the ego in personality development. Humanistic theories of personality have themselves helped fuel research in positive psychology, which focuses on character strengths such as wisdom, courage, and humanity, as well as on happiness, thriving, and other aspects of human experience associated with maximum personal development and functioning (Peterson, 2006a; Fredrickson & Cohn, 2008; Seligman, 2002).

Prominent Humanistic Theories

By far the most prominent humanistic theories of personality are those of Carl Rogers and Abraham Maslow.

Rogers’s Self Theory In his extensive writings, Carl Rogers (e.g., 1961, 1970, 1980) emphasized the **actualizing tendency**, which he described as an innate inclination toward growth and fulfillment that motivates all human behavior and is expressed in a unique way by each individual (Raskin & Rogers, 2001). Rogers considered personality the expression of that actualizing tendency as it unfolds in each individual’s uniquely perceived reality (Feist & Feist, 2009). The centerpiece of Rogers’s theory is the *self,* the part of experience that a person identifies as “I” or “me.” According to Rogers, those who accurately experience the self—with all its preferences, abilities, fantasies, shortcomings, and desires—are on the road to what Kurt Goldstein (1939) had called *self-actualization.* For people whose experiences of the self become distorted, however, progress toward self-actualization is likely to be slowed or stopped.

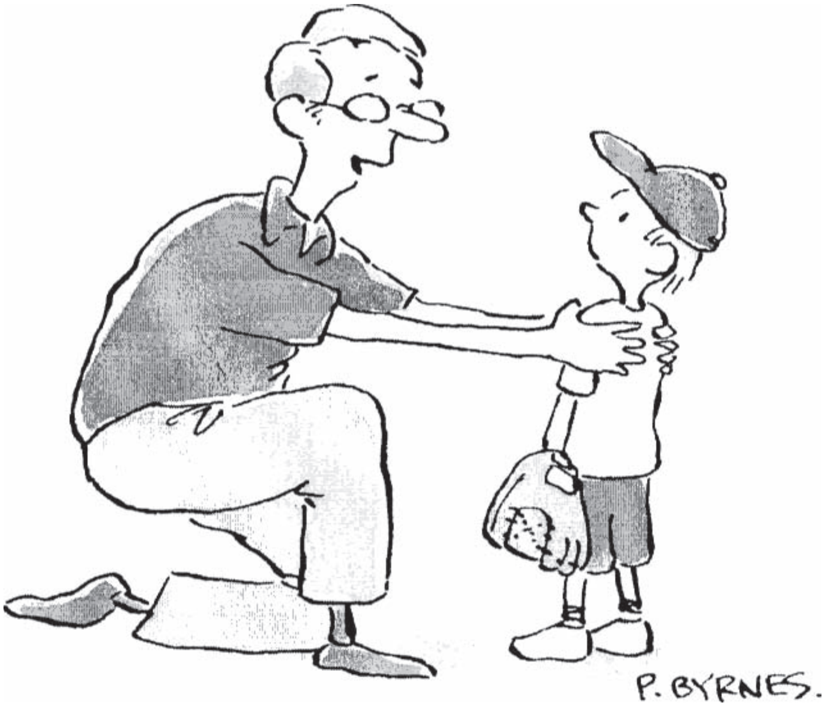
Rogers saw personality development beginning early, as children learn to need other people’s approval, or as he called it, *positive regard.* Evaluations by parents, teachers, and others soon begin to affect children’s self-evaluations. When these evaluations are in agreement with a child’s own self-evaluations, the child reacts in a way that matches, or is *congruent* with, self-experience. The child not only experiences positive regard but also evaluates the self as “good” for having earned approval. This positive self-experience becomes part of the **self-concept**, which is the way one thinks of oneself. But what if a positive self-experience is evaluated negatively by others, as when a little boy is teased by his father for having fun playing with dolls? In this case, the child must either do without a parent’s positive regard or, more likely, reevaluate the self-experience—deciding perhaps that “I don’t like dolls” or “Feeling good is bad.”

In other words, said Rogers, personality is shaped partly by the actualizing tendency and partly by evaluations made by others. In this way, people come to like what they are “supposed” to like and to behave as they are “supposed” to behave. This socialization process is adaptive, because it helps people function in society, but it often requires that they suppress their self-actualizing tendency and distort their experience. Rogers argued that psychological discomfort, anxiety, or even mental disorder can result when the feelings people experience or express are *incongruent,* or at odds, with their true feelings.

actualizing tendency According to Carl Rogers, an innate inclination toward growth that motivates all people.

self-concept The way one thinks of oneself.

Parents are not usually this obvious about creating conditions of worth, but according to Carl Rogers, the message gets through in many more subtle ways.



© Pat Byrnes/The New Yorker Collection/www.cartoonbank.com

"Just remember, son, it doesn't matter whether you win or lose—unless you want Daddy's love."

Incongruence is likely, said Rogers, when parents and teachers act in ways that lead children to believe that their worth as people depends on displaying the "right" attitudes, behaviors, and values. These **conditions of worth** are created whenever *people* are evaluated instead of their behavior. For example, parents who find their toddler smearing fingerpaint on the dog are unlikely to say, "I love you, but I don't approve of this particular behavior." They are more likely to shout, "Bad boy!" or "Bad girl!" This reaction sends a message that the child is lovable and worthwhile only when well behaved. As a result, the child's self-experience is not "I like painting Fang, but Mom and Dad don't approve," but instead, "Playing with paint is bad, and I am bad if I like it, so I don't like it," or "I like it, so I must be bad." The child may eventually display overly neat and tidy behaviors that do not reflect the real self but rather are part of the ideal self that is dictated by the parents.

As with Freud's concept of superego, conditions of worth are first set up by external pressure but eventually become part of the person's belief system. So Rogers considered rewards and punishments important in personality development not just because they shape overt behavior but also because they can so easily lead to distorted self-perceptions and incongruence (Roth et al., 2009).

Maslow's Growth Theory Like Rogers, Abraham Maslow (1954, 1971) regarded personality as the expression of a basic human tendency toward growth and self-actualization. In fact, Maslow believed that self-actualization is not just a human capacity but a human need. As described in the motivation and emotion chapter, he placed self-actualization as the highest in a hierarchy of motives, or needs. Yet, said Maslow, people are often distracted from seeking self-actualization because they focus on needs that are lower on the hierarchy.

Maslow believed that most people are controlled by **deficiency motivation**, the preoccupation with perceived needs for material things, especially things they do not have. Ultimately, he said, deficiency-motivated people come to see life as a meaningless exercise in disappointment and boredom, and they may begin to behave in problematic ways. For example, in an attempt to satisfy the need for love and belongingness, people may focus on what love can give them (security) and not on what they can give

conditions of worth According to Carl Rogers, the feelings an individual experiences when an evaluation is applied to the person rather than to the person's behavior.

deficiency motivation According to Abraham Maslow, a preoccupation with perceived needs for things a person does not have.

The Joys of Growth Motivation

According to Abraham Maslow's theory of personality, the key to personal growth and fulfillment lies in focusing on what we have, not on what we don't have or on what we have lost. Rachel Barton Pine could have let the accident that took her leg destroy her career as a concert violinist and with it her joy in life—but she didn't. You can find out more about her life in music at http://www.rachelbartonpine.com. Researchers in the field of positive psychology are studying the development of resilience, as well as other character strengths, as part of an effort to understand and promote all the things that can go right in human life (Peterson, 2006a).

to another person. This deficiency orientation may lead a person to be jealous and to focus on what is missing in relationships. As a result, the person will never truly experience either love or security.

In contrast, people with **growth motivation** do not focus on what is missing but draw satisfaction from what they have, what they are, and what they can do. This orientation opens the door to what Maslow called *peak experiences,* in which people feel joy, even ecstasy, in the mere fact of being alive, being human, and knowing that they are realizing their fullest potential.

Evaluating the Humanistic Psychology Approach

The humanistic psychology approach to personality is consistent with the way many people view themselves. It gives a central role to each person's immediate experiences and emphasizes the uniqueness of each individual. The humanistic approach and its phenomenological perspective inspired the person-centered therapy of Rogers and other forms of psychotherapy (see the chapter on treatment of psychological disorders). This approach also underlies various short-term personal growth experiences—such as sensitivity training and encounter groups designed to help people become more aware of themselves and the way they relate to others (e.g., Cain & Seeman, 2002). It has led to programs designed to teach parents how to avoid creating conditions of worth while maximizing their children's potential. And as already mentioned, the humanistic approach has helped promote research in positive psychology, which studies what and how things go right in human development (Diener, Oishi, & Lucas, 2009; Peterson, 2006a, 2006b; Snyder & Lopez, 2006).

Yet to some observers, the humanistic view is naive, romantic, and unrealistic. Are people all as inherently good and growth-oriented as this approach suggests? Critics wonder about that, and they also fault humanistic personality theories for paying too little attention to the importance of inherited characteristics, learning, situational influences, and unconscious motivation in shaping personality. The idea that everyone is directed only by an innate growth potential is viewed by these critics as an oversimplification. So, too, is the assumption that all human problems stem from blocked actualization. Like the trait approach, humanistic theories seem to do a better job of describing personality than explaining it. And like many of the concepts in psychodynamic theories, humanistic concepts seem too vague to be tested empirically. Accordingly, the humanistic approach has not been very popular among psychologists who rely on empirical research to learn about personality (Feist & Feist, 2009). This may be changing, though, as the explosion of research in positive psychology leads

growth motivation According to Abraham Maslow, a tendency to draw satisfaction from what is available in life, rather than to focus on what is missing.

to new humanistically oriented theories that lend themselves to empirical evaluation (e.g., Burton et al., 2006; Cohn et al., 2009; Waugh, Fredrickson, & Taylor, 2008).

Even so, humanists' tendency to define ideal personality development in terms of personal growth, independence, and self-actualization has been criticized for emphasizing culture-specific ideas about mental health that may not apply outside North America and other Western cultures (Heine & Buchtel, 2009). As described in the next section, the individualist foundations of humanistic personality theories may be in direct conflict with the values of non-Western, collectivist cultures.

"In Review: Major Approaches to Personality" summarizes key features of the humanistic psychology approach, along with those of the other approaches we have described. Which approach is most accurate? There is no simple answer to that question, partly because each approach emphasizes different aspects of personality. Accordingly, it has been suggested that a full understanding of the origins and development of personality will come only by recognizing the roles of all the factors that various approaches have shown to be important (Mayer, 2005; McAdams & Pals, 2006).

IN REVIEW Major Approaches to Personality

Approach	Basic Assumptions About Behavior	Typical Research Methods
Psychodynamic	Determined by largely unconscious intrapsychic conflicts	Case studies
Trait	Determined by traits or needs	Analysis of tests for basic personality dimensions
Social-cognitive	Determined by learning, cognitive factors, and specific situations	Analysis of interactions between people and situations
Humanistic	Determined by innate growth tendency and individual perception of reality	Studies of relationships between perceptions and behavior

1. **Tests that measure the five-factor personality model's dimensions are based on the ____________ approach to personality.**
2. **The role of learning is most prominent in the ____________ approach to personality.**

LINKAGES

LINKAGES Does culture determine personality? (a link to Human Development, p. 508)

Personality, Culture, and Human Development

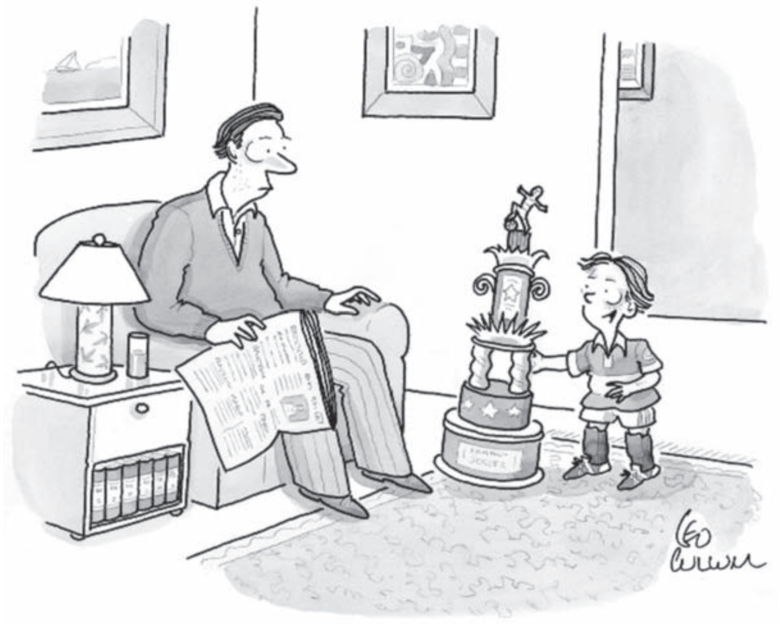
In many Western cultures, it is common to hear people encourage others to "stand up for yourself" or to "blow your own horn" in order to "get what you have coming to you." In middle-class North America, for example, the values of achievement and personal distinction are taught to children, particularly male children, very early in life (Kitayama, Duffy, & Uchida, 2007). North American children are encouraged to feel special, to want self-esteem, and to feel good about themselves, partly because these characteristics are associated with happiness, popularity, and superior performance in school. Whether self-esteem is the cause or the result of these good outcomes (Baumeister et al., 2003), children who learn and display these values nevertheless tend to receive praise and encouragement for doing so.

As a result of this cultural training, many people in North America and Europe develop personalities that are largely based on a sense of high self-worth. In a study by Hazel Markus and Shinobu Kitayama (1997), for example, 70 percent of a sample of U.S. students believed they were superior to their peers, and 60 percent believed they were in the top 10 percent on a wide variety of personal attributes! This tendency toward self-enhancement is evident as early as age 4.

Many Western personality theorists regard a sense of independence, uniqueness, and self-esteem as fundamental to mental health. As noted in the chapter on human development, for example, Erik Erikson included the appearance of personal identity and self-esteem as part of normal psychosocial development. Middle-class Americans who fail to value and strive for independence, self-promotion, and unique personal achievement may be thought to have a personality disorder, some form of depression, or other psychological problems.

Are these ideas based on universal truths about personality development, or do they reflect the values of the cultures that generated them? It is certainly clear that people in many non-Western cultures develop personal orientations that are different from those of North Americans and Europeans (Heine & Buchtel, 2009; Lehman, Chiu, & Schaller, 2004). In China and Japan, for example, an independent, unique self is not emphasized (Ho & Chiu, 1998). Children there are encouraged to develop and maintain harmonious relations with others and not to stand out from the crowd because doing so might make others seem inferior by comparison. So whereas children in the United States hear that "the squeaky wheel gets the grease" (meaning that you don't get what you want unless you ask for it), Japanese children are warned that "the nail that stands out gets pounded down" (meaning that it is not a good idea to draw attention to yourself). From a very young age, Japanese children are taught to be modest, to play down the value of personal contributions, and to appreciate the joy and value of group work (Kitayama & Uchida, 2003).

In contrast to the *independent* self-system prevalent in individualist cultures such as the United States, the United Kingdom, and Switzerland, countries characterized by a more collectivist orientation (e.g., Japan, China, Brazil, and Nigeria) promote an *interdependent* self-system in which people perceive themselves as a small fraction of a social whole. Each person has little or no meaningful definition without reference to the group. These differences in self-systems may produce differences in what gives people a sense of well-being and satisfaction (Tsai, Knutson, & Fung, 2006). In the United States, a sense of personal well-being is typically associated with the feeling of *having positive attributes,* such as intelligence, creativity, competitiveness, and persistence. In Japan and other Asian countries, it is more likely to be associated with the feeling of *having no negative attributes* (Eliot et al., 2001). Similarly, the results of studies conducted with thousands of people around the world indicate that in collectivist



"We lost!"

The goal of esteem building is clear these days in many children's activities at school and in some team sports, too, which are designed either to eliminate competition or, as in this case, ensure that everyone feels like a winner. The same goal is reflected in day care centers, summer camps, and other children's programs with names such as Starkids, Little Wonders, Superkids, and Precious Jewels.

Culture and Personality

TRY THIS In individualist cultures, most children learn early that personal distinction is valued by parents, teachers, and peers. In cultures that emphasize collectivist values, a strong sense of personal self-worth tends to be regarded as less important. In other words, the features of "normal" personality development vary from culture to culture. Make a list of the core values you have learned. Which of them are typical of individualist cultures, which are typical of collectivist cultures, and which reflect a combination of both?

© AP Photo

cultures, life satisfaction is associated with social approval and harmonious relations with others, whereas in individualist cultures, life satisfaction is associated with high self-esteem and feeling good about one's own life (Uchida et al., 2001).

Because cultural factors shape notions about ideal personality development, it is important to evaluate various approaches to personality in terms of how well they apply to cultures other than the one in which they were developed (Church, 2001; Cross & Markus, 1999). Their applicability to males and females must also be considered. Even within North American cultures, for example, there are gender differences in the development of self-esteem. Females tend to display an interdependent self-system, achieving their sense of self and self-esteem from attachments to others. By contrast, males' self-esteem tends to develop in relation to personal achievement, in a manner more in keeping with an independent self-system (Cross & Madson, 1997). Cross-gender and cross-cultural differences in the nature and determinants of a sense of self underscore the pervasive effects of gender and culture on the development of many aspects of personality (Acerbi, Engquist, & Ghirlanda, 2009; Matsumoto, Yoo, & Nakagawa, 2008; Zakriski, Wright, & Underwood, 2005).

FOCUS ON RESEARCH METHODS

Longitudinal Studies of Temperament and Personality

Studying the development of personality over the life span requires longitudinal research, in which the same people are followed from infancy to adulthood so that their characteristics can be assessed at different points in their lives. A number of studies have used longitudinal methods to explore a variety of questions about changes in personality over time.

What was the researchers' question?

The specific question addressed by Avshalom Caspi and his colleagues was whether the temperament children display at birth and in their early years predicts their personality and behavior as adults (Caspi, 2000; Caspi, Harrington, et al., 2003; Caspi & Silva, 1995; Caspi et al., 1995, 1997). As discussed in the chapter on human development, it is generally agreed that differences in temperament are influenced more by heredity than by the environment (Clark & Watson, 2008).

How did the researchers answer the question?

Caspi's research team studied all the children born in Dunedin, New Zealand, between April 1972 and March 1973—a total of about a thousand individuals. When the children were 3 years old, an examiner gave each of them a test of their cognitive abilities and motor skills and, using a 3-point scale, rated their reactions to the testing situation. Some of the children displayed uncontrolled behaviors; some interacted easily; some were withdrawn and unresponsive. (To avoid bias while making their ratings, the examiners were told nothing about the children's typical behavior outside of the testing room.) These observations were used to place each child into one of five temperament categories: *undercontrolled* (irritable, impatient, emotional), *inhibited* (shy, fearful, easily distracted), *confident* (eager to perform, responsive to questions), *reserved* (withdrawn, uncomfortable), and *well adjusted* (friendly, well controlled). The children were observed and categorized again when they were 5, 7, and 9 years old. On each occasion, a different person did the ratings, thus ensuring that the observers' ratings would not be biased by earlier impressions. Almost all correlations among the independent ratings made at various ages were positive and statistically significant, indicating that the temperament classifications were stable across time.

When the participants were 18 years old, they completed a standard personality test, and at 21, they were interviewed about the degree to which they engaged in risky and unhealthy behaviors such as excessive drinking, violent crime, unprotected sexual activity, and unsafe driving habits. To avoid bias, the interviewers were given no information about the participants' temperament when they were children or about their scores on the personality test. Finally, at the age of 26, the participants again took a standard personality test and were also rated by their friends on the Big Five personality dimensions.

What did the researchers find?

Several significant differences were found among the average personality scores for the five original temperament categories. For example, the average test scores of 26-year-olds who had been classified as "undercontrolled" in childhood showed that they were more alienated, uninhibited, and stressed than any other temperament group. Further, people who had been classified as "confident" or "well adjusted" as children tended to be better adjusted and more extraverted at 26 than people who had been classified as "inhibited" or "reserved" when they were children. Young adults who as children had been classified as "well adjusted" tended to be effective individuals who were likely to assume leadership roles. These findings held true for males and females alike.

There were also small but significant correlations between early temperament and health-risk and criminal behaviors (Caspi, Harrington, et al., 2003). For example, people classified as "overcontrolled" were more likely to avoid dangerous and exciting activities at the age of 21 than those who had been classified as "undercontrolled." In fact, participants classified as "undercontrolled" were significantly more likely than any of the other groups to engage in risky behaviors and to have criminal records. The relationship between temperament in childhood and health-risk behaviors in young adulthood was not a direct one, though. Statistical analyses revealed that temperament at age 3 affected personality at age 18, which in turn affected later behavior patterns.

What do the results mean?

The results of Caspi's studies provide persuasive empirical support for a hypothesis long endorsed by personality psychologists, namely, that we can make relatively accurate predictions about adult personality and behavior if we know about childhood temperament (e.g., Glenn et al., 2007). But as critical thinkers, we must be careful not to overstate the strength of these results. Although the correlations between temperament and personality and between temperament and various problematic behaviors were statistically significant, they were also relatively small. For example, not all the participants classified as "undercontrolled" at age 3 turned out to be aggressive or violent at age 21. The implication is that personality is influenced and shaped by temperament but not completely determined by it (Clark & Watson, 2008; Roberts, Walton, & Viechtbauer, 2006).

The results of these studies also confirm a point made in the chapter on health, stress, and coping—that personality plays a significant role in health. Specifically, personality characteristics predispose people to engage in behaviors that can affect their mental and physical health.

What do we still need to know?

Caspi's research has revealed some consistency between temperament in childhood and personality in adulthood, but it also leaves some unanswered questions (Roberts & Delvecchio, 2000). For example, what factors underlie this consistency? The fact that there are individual differences in adult behavior within temperament groups shows that a child is not simply biologically programmed to display certain personality traits later (Hampson, 2008). One explanation offered by Caspi and his colleagues draws heavily on social-cognitive theories, particularly on Bandura's notion of reciprocal determinism. These researchers believe that long-term consistencies in behavior result from the mutual influence that temperament and environmental events have on one another. They propose, for example, that people tend to put themselves in situations that reinforce their temperament. So "undercontrolled" people might choose to spend time with people who accept and even encourage rude or impolite behavior. And when such behavior brings negative reactions, the world seems that much more hostile, and they become even more aggressive and negative. Caspi and his colleagues (2003) regard the results of their studies as evidence that this process of mutual influence between personality and situations can continue over a lifetime.

Assessing Personality

We all want to know something about our own personality and other people's, too, so it is no wonder that various kinds of personality assessments are widely available in newspapers and magazines and on the Internet. For example, there is a Web site called TweetPsych that offers personality profiles of frequent Twitter users based on the content of their tweets. Information available on Facebook and MySpace has also been used to assess various personality dimensions (Back et al., 2010), but psychologists usually describe people's personalities using information from four main sources: *life outcomes* (such as level of education, income, or marital status), *situational tests* (laboratory measurements of behavioral, emotional, and physiological reactions to conflict, frustration, and the like), *observer ratings* (judgments about a person made by family or friends), and *self-reports* (responses to interviews and personality tests). The data gathered through these methods are used for many purposes, including diagnosing psychological disorders, predicting dangerousness, selecting new employees, and even choosing astronaut candidates best suited to space travel (Kramer, Bernstein, & Phares, 2009; Meyer et al., 2001).

Life outcomes, observer ratings, and situational tests allow direct assessment of many aspects of behavior, including how often, how effectively, and how consistently various actions occur. *Interviews* provide a way to gather information about personality from the person's own point of view. Some interviews are *open-ended,* meaning that questions are tailored to the intellectual level, emotional state, and special needs of the person being interviewed. Others are *structured,* meaning that the interviewer asks a fixed set of questions about specific topics in a particular order. Structured interviews are routinely used in personality research because they are sure to cover matters of special interest to the researcher.

Personality tests offer a way of gathering self-report information that is more standardized and economical than interviews. To be useful, however, a personality test must be reliable and valid. As described in the chapter on cognitive abilities, reliability refers to how stable or consistent the results of a test are; validity reflects the degree to which test scores are interpreted appropriately and used properly in making inferences about people. The many personality tests available today are traditionally classified as either *projective* or *nonprojective* measures of personality.

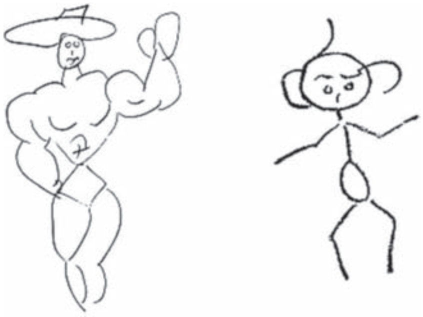

FIGURE 14.5

A Draw-a-Person Test

These drawings were done by an 18-year-old male who had been caught stealing a television set. A psychologist interpreted the muscular figure as the young man's attempt to boast of masculine prowess but saw the muscles' "puffy softness" as suggesting feelings of inadequacy. The drawing of the babylike figure was seen to reveal vulnerability, dependency, and a need for affection. Appealing as these interpretations may be, research does not generally support the value of projective tests in personality assessment (Lilienfeld, Wood, & Garb, 2000).

Projective Personality Measures

Projective personality measures contain items or tasks that are ambiguous, meaning that they can be perceived in many different ways. People taking projective tests might be asked to draw a house, a person, a family, or a tree (see Figure 14.5); to fill in the missing parts of incomplete pictures or sentences; to say what they associate with particular words; or to report what they see in a drawing or picture. Projective techniques are sometimes used in personality research, but they are far more popular among psychodynamically oriented clinical psychologists, who use them to assess psychological disorders (Garb et al., 2005). These psychologists believe that people's responses to projective tests are guided by unconscious needs, motives, fantasies, conflicts, thoughts, and other hidden aspects of personality.

One prominent projective test, developed by Henry Murray and Christina Morgan, is called the Thematic Apperception Test, or TAT. As described in the chapter on motivation and emotion, the TAT is used to measure need for achievement (see Figure 11.5 in that chapter). It is also used to assess other needs (e.g., for power or affiliation) that Murray and Morgan considered the basis for personality. Another widely used projective test, the Rorschach Inkblot Test, asks people to say what they see in a series of inkblots similar to the one in Figure 14.6.

Psychologists who support the use of projective tests claim that ambiguous test items make it difficult for respondents to detect what is being measured and what the "best" answers would be. They argue, therefore, that these tests can measure aggressive and sexual impulses and other personality features that people might otherwise be able to hide. However, in comparison with the results of nonprojective tests, responses to projective tests are much more difficult to translate into numerical scores for scientific analysis. In an effort to reduce the subjectivity involved in projective-test interpretation, some psychologists have developed more structured—and thus potentially more reliable—scoring systems for instruments such as the Rorschach (Erdberg, 1990; Exner, 2003). And there are in fact specific instances—as in studies assessing implicit social motives with the TAT—in which projective tests show acceptable reliability and validity (Meyer, Mihura, & Smith, 2005; Schultheiss, 2008; Schultheiss & Rohde, 2002). Overall, though, projective personality tests are substantially less reliable and valid than nonprojective tests (Garb et al., 2005; Hunsley, Lee, & Wood, 2003; Lilienfeld, Wood, & Garb, 2000). In fact, because of their generally poor ability to predict behavior, projective tests may add little information about people that goes beyond what might be inferred from interviews and nonprojective personality measures (Hunsley, Lee, & Wood, 2003).

Nonprojective Personality Measures

Nonprojective personality measures, also known as *objective personality measures,* contain clearly stated items that relate to a person's thoughts, feelings, or behavior (such as "Do you like parties?"). Responses to these items are used to guide conclusions about the individual's personality. The most common kind of objective personality test is similar in format to the multiple-choice or true-false examinations used in many classrooms. Like those exams, self-report personality tests can be administered to many people at the same time. They can also be machine-scored. However, whereas there is only one correct answer for each item on a classroom exam, the "correct" answers to an objective personality test depend on who is taking it. Each person is asked to respond in a way that best describes him or her.

The person's responses to an objective test's items are combined into a score. That score can be used to draw conclusions about the individual's personality, but only after it has been compared with the responses of thousands of other people who have taken the same test. For example, before interpreting your score on a self-report test of extraversion, a psychologist would compare that score with *norms,* or average scores from other individuals of your age and gender. Only if you were well above these averages would you be considered unusually extraverted.

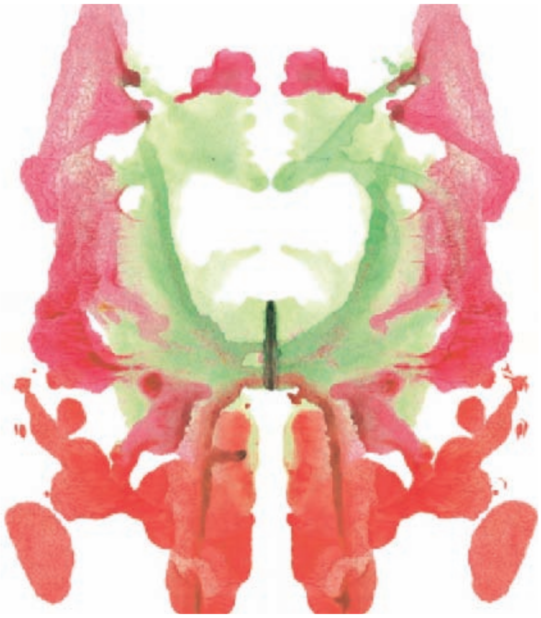
projective personality measures Personality assessments made up of ambiguous stimuli that can be perceived and responded to in many different ways.

nonprojective personality measures Paper-and-pencil tests containing direct, unambiguous items relating to the personality of the individual being assessed.

FIGURE 14.6

The Rorschach Inkblot Test

TRY THIS The Rorschach test consists of ten patterns similar to this one, some in color, some in black and white. People taking the test are asked to say what each pattern might be and to explain why. Jot down what you see in this inkblot and why, and then compare your responses to those of some friends. Most scoring methods focus on (1) what part of the blot the person responds to; (2) what details, colors, or other features appear to determine each response; (3) the content of responses (such as seeing animals, maps, or body parts); and (4) the popularity or commonness of the responses.



© Charlotte Miller

Some nonprojective personality measures focus on one particular trait, such as optimism (Carver & Scheier, 2002). Others measure a set of related traits, such as empathy and social responsibility (Penner & Orom, 2009). Still others measure the strength of a wider variety of traits to reveal general psychological functioning. For example, the Neuroticism-Extraversion-Openness Personality Inventory, Revised, or NEO-PI-R (Costa & McCrae, 1992), is designed to measure the Big Five personality factors described earlier. Table 14.3 shows how the test's results are presented. One innovative feature of the NEO-PI-R is its "private" and "public" versions. The first version asks for the respondent's self-assessment. The second version asks a person who knows the respondent to rate him or her on various dimensions. Personality descriptions based

TABLE 14.3 Sample Summary of Results from the NEO-PI-R

The NEO-PI-R assesses the Big Five personality dimensions. In this example of the results a respondent might receive, the five factors scored are, from the top row to the bottom row, neuroticism, extraversion, openness, agreeableness, and conscientiousness. Because people with different NEO profiles tend to have different psychological problems, this test has been used to aid in the diagnosis of personality disorders (Trull & Sher, 1994).

Compared with the responses of other people, your responses suggest that you can be described as:

☐ Sensitive, emotional, and prone to experience feelings that are upsetting.	☒ Generally calm and able to deal with stress, but you sometimes experience feelings of guilt, anger, or sadness.	☐ Secure, hardy, and generally relaxed even under stressful conditions.
☐ Extraverted, outgoing, active, and high-spirited. You prefer to be around people most of the time.	☐ Moderate in activity and enthusiasm. You enjoy the company of others, but you also value privacy.	☒ Introverted, reserved, and serious. You prefer to be alone or with a few close friends.
☐ Open to new experiences. You have broad interests and are very imaginative.	☐ Practical but willing to consider new ways of doing things. You seek a balance between the old and the new.	☒ Down-to-earth, practical, traditional, and pretty much set in your ways.
☐ Compassionate, good-natured, and eager to cooperate and avoid conflict.	☒ Generally warm, trusting, and agreeable, but you can sometimes be stubborn and competitive.	☐ Hardheaded, skeptical, proud, and competitive. You tend to express your anger directly.
☒ Conscientious and well organized. You have high standards and always strive to achieve your goals.	☐ Dependable and moderately well organized. You generally have clear goals but are able to set your work aside.	☐ Easygoing, not very well organized, and sometimes careless. You prefer not to make plans.

on the two versions are often quite similar, but discrepancies may indicate problems. For example, if a person's self-ratings are substantially different from those of a spouse, marital problems may be indicated. The nature of the discrepancies could suggest a focus for marital therapy.

The NEO-PI-R is quite reliable (Costa & McCrae, 2008), and people's scores on its various dimensions have been successfully used to predict social status (Anderson et al., 2001), as well as a number of behaviors, including success in business, performance in specific jobs (Conte & Gintoft, 2005; Zhao & Seibert, 2006), and the likelihood of engaging in criminal activities and risky sexual behaviors (Miller et al., 2004).

LINKAGES Can personality tests be used to diagnose mental disorders? (a link to Psychological Disorders, p. 603)

When the goal of personality testing is to diagnose psychological disorders, the most commonly used objective test is the Minnesota Multiphasic Personality Inventory, or MMPI (Butcher, 2006). The original 566-item true-false test was developed during the 1930s at the University of Minnesota by Starke Hathaway and J. C. McKinley. It has now been revised and updated to become the MMPI-2 RF (restructured form; Ben-Porath & Tellegen, 2008). The MMPI's items are organized into ten *clinical scales*. These are groups of items that in earlier research had drawn a characteristic pattern of responses only from people who displayed particular psychological disorders or personality characteristics. The MMPI-2 RF also contains several validity scales. Responses to these scales detect whether respondents are distorting their answers, misunderstanding the items, or being uncooperative. For example, someone who responds "true" to items such as "I never get angry" may not be giving honest answers to the test as a whole.

Interpreting the MMPI is largely a matter of using computer programs to compare test profiles—such as those shown in Figure 14.7—to the profiles of people already known to display certain personality characteristics. It is presumed that people share characteristics with the group whose profile most closely resembles their own. But although a very high score on one scale, such as depression, might indicate a problem in the dimension measured by that scale, MMPI interpretation usually focuses on the overall pattern in the clinical scales—particularly on the combination of two or three scales on which a person has unusually high scores.

There is considerable evidence for the reliability and validity of MMPI clinical scales (Forbey & Ben-Porath, 2008), but even the latest editions of the test are far from perfect measurement tools (Carr, Moretti, & Cue, 2005; Munley, 2002; Rouse, 2007). The validity of MMPI interpretations may be particularly suspect when, because of cultural factors, the perceptions, values, and experiences of a respondent are notably different from those of the test developers and the people to whom the respondent's results are compared. A profile that looks typical of people with a certain disorder might actually reflect the culture-specific way the respondent interpreted the test items rather than a mental problem (Butcher, 2004; Groth-Marnat, 1997). Even though the MMPI-2 RF uses comparison norms that represent a more culturally diverse population than the original MMPI did, psychologists must always use caution when interpreting profiles of people who are members of minority subcultures (Butcher, 2004).

("In Review: Personality Tests" summarizes the characteristics of projective and nonprojective measures, along with some of their advantages and disadvantages.)

Personality Tests and Employee Selection

How good are personality tests at selecting people for jobs? Most industrial and organizational psychologists believe that these tests are valuable tools in the selection of good employees. The MMPI (and even some projective tests) are occasionally employed for such purposes (e.g., Matyas, 2004), but the majority of personality tests used by large organizations are those that measure the Big Five personality dimensions or related characteristics (Borman, Hanson, & Hedge, 1997; Costa, 2001). Several researchers have found significant relationships between scores on these characteristics and

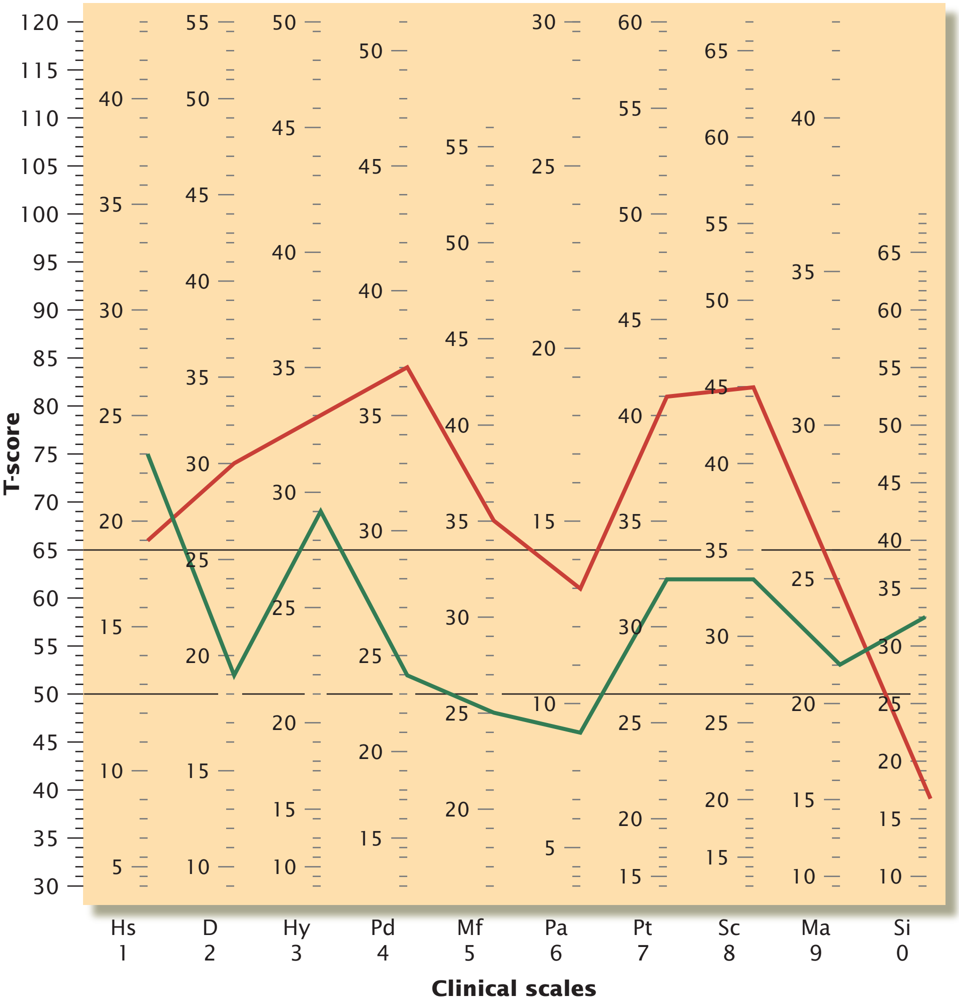


FIGURE 14.7

MMPI Clinical Scales and Sample Profiles

A score of 50 on the clinical scales of the MMPI is average. Scores at or above 65 mean that the person's responses on that scale are more extreme than at least 95 percent of the normal population. The red line represents the profile of Kenneth Bianchi, the "Hillside Strangler," who murdered thirteen women in the late 1970s. His profile is characteristic of a shallow person with poor self-control and little personal insight who is sexually preoccupied and unable to reveal himself to others. The profile in green comes from a more normal man, but it is characteristic of someone who is self-centered, passive, unwilling to accept personal responsibility for his behavior, and, when under stress, complains of numerous vague physical symptoms. The clinical scales abbreviated in the figure are as follows:

1. Hypochondriasis (Hs; concern with bodily functions and symptoms)
2. Depression (D; pessimism, hopelessness, slowed thinking)
3. Hysteria (Hy; use of physical or mental symptoms to avoid problems)
4. Psychopathic deviate (Pd; disregard for social customs, emotional shallowness)
5. Masculinity/femininity (Mf; interests associated with a particular gender)
6. Paranoia (Pa; delusions, suspiciousness)
7. Psychasthenia (Pt; worry, guilt, anxiety)
8. Schizophrenia (Sc; bizarre thoughts and perceptions)
9. Hypomania (Ma; overactivity, excitement, impulsiveness)
10. Social introversion (Si; shy, insecure)

measures of overall job performance and effective leadership (Hirschfeld et al., 2008; Kieffer, Schinka, & Curtiss, 2004; Lim & Ployhart, 2004; Motowidlo, Brownlee, & Schmit, 2008; Silverthorne, 2001). A more general review of studies involving thousands of people has shown that nonprojective personality tests are of value in helping businesses reduce thefts and other disruptive employee behaviors (Berry, Sackett, & Wiemann, 2007; Hogan, 2006; Ones & Viswesvaran, 2001; Ones, Viswesvaran, & Schmidt, 2003).

Still, personality tests are not perfect, and as noted earlier, they sometimes lead to incorrect predictions about behavior. Many tests measure traits that may be too general to predict specific aspects of job performance (Berry, Sackett, & Wiemann, 2007; Furnham, 2001). In fact, features of the work situation are often better predictors of employee behavior than personality tests are (Mumford et al., 2001). Further, some employees consider personality tests an invasion of their privacy. They worry also that test results in their personnel files might later be misinterpreted and hurt their chances for promotion or for employment by other companies. Lawsuits have resulted in a ban on the use of personality tests in the selection of U.S. federal employees. Concerns about privacy and other issues surrounding personality testing have also led the American Psychological Association and other organizations to publish joint ethical standards relating to procedures for the development, dissemination, and use of all psychological tests (American Educational Research Association, American

Psychological Association, and National Council on Measurement in Education, 1999; American Psychological Association, 2002b). The goal is not only to improve the reliability and validity of tests but also to ensure that their results are properly used and do not infringe on individuals' rights (Turner et al., 2001).

IN REVIEW Personality Tests

Type of Test	Characteristics	Advantages	Disadvantages
Projective	Ambiguous stimuli allow maximum freedom of response; scoring is subjective, though some objective methods exist	"Correct" answers not obvious; designed to tap unconscious impulses; flexible use	Reliability and validity lower than those of nonprojective tests
Nonprojective	Direct questions presented in paper-and-pencil format; quantitatively scored	Efficiency, standardization	Subject to deliberate distortion

1. Projective personality measures are based on the ____________ approach to personality.

2. The NEO-PI-R and the MMPI-2 RF are examples of ____________ tests.

3. Most personality researchers use ____________ tests in their work.

LINKAGES

As noted in the chapter on introducing psychology, all of psychology's many subfields are related to one another. Our discussion of cultural factors and personality illustrates just one way in which the topic of this chapter, personality, is linked to the subfield of developmental psychology (which is the focus of the chapter on human development). The Linkages diagram shows ties to two other subfields as well, and there are many more ties throughout the book. Looking for linkages among subfields will help you see how they all fit together and better appreciate the big picture that is psychology.

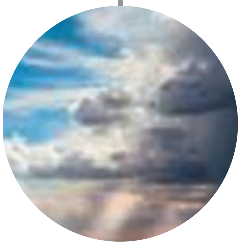
CHAPTER 10
Cognitive Abilities

CHAPTER 12
Human Development



CHAPTER 16
Treatment of Psychological Disorders

SUMMARY

Personality refers to the unique pattern of psychological and behavioral characteristics by which each person can be compared and contrasted with other people. The four main theoretical approaches to personality are psychodynamic, trait, social-cognitive, and humanistic.

The Psychodynamic Approach

The *psychodynamic approach*, first proposed by Sigmund Freud, assumes that personality arises out of the interplay of various unconscious psychological processes.

The Structure and Development of Personality

Freud believed that personality has three components—the *id*, which has a reservoir of *libido* and operates according to the *pleasure principle*; the ego, which operates according to the *reality principle*; and the *superego*, which internalizes society's rules and values. The ego uses *defense mechanisms* to prevent unconscious conflicts among these components from becoming conscious and causing anxiety or guilt. Freud proposed that the focus of conflict changes as the child passes through five stages of *psychosexual development*: the *oral stage*, the *anal stage*, the *phallic stage* (during which the *Oedipal complex* or the *Electra complex* arises), the *latency period*, and the *genital stage*.

Variations on Freud's Personality Theory

Many of Freud's early followers developed new theories that differed from his. Among these theorists were Carl Jung, Alfred Adler, and Karen Horney. These and other theorists tended to downplay the role of instincts and the unconscious, emphasizing instead the importance of conscious processes, ego functions, and social and cultural factors. Horney also challenged the male-oriented nature of Freud's original theory.

Contemporary Psychodynamic Theories

Current psychodynamic theories are derived from the neo-Freudians' emphasis on family and social relationships. According to object relations and attachment theorists, personality development depends mainly on the nature of early interactions between individuals and their caregivers.

Evaluating the Psychodynamic Approach

Despite evidence in support of some psychodynamic concepts and recent attempts to test psychodynamic theories more precisely and objectively, critics still fault the approach for its lack of a scientific base and for its view of human behavior as driven by unmeasurable forces.

The Trait Approach

The *trait approach* to personality assumes that personality is made up of stable internal characteristics that appear at varying strengths in different people and guide their thoughts, feelings, and behavior.

Allport's Trait Theory

Gordon Allport believed that personality is created by a small set of central traits and a larger number of secondary traits in each individual. He analyzed language to try to identify those traits, thus laying the foundation for modern research on personality traits.

The Five-Factor Model of Personality

Building on the work of Allport and Raymond Cattell, contemporary researchers have used factor analysis to identify five basic dimensions of personality, collectively referred to as the *five-factor* (*or Big Five*) *personality model*. These dimensions—openness to experience, conscientiousness, extraversion, agreeableness, and neuroticism—have been found in many different cultures.

Biological Trait Theories

Hans Eysenck believed that differences in nervous system arousal are responsible for differences in core dimensions of personality, especially introversion–extraversion and emotionality–stability. Newer biological theories such as Jeffrey Gray's reinforcement sensitivity theory, have largely replaced Eysenck's theory, and they suggest instead that these differences are due to biological differences in the sensitivity of brain systems involved with responsiveness to rewards and to punishments.

Evaluating the Trait Approach

The trait approach has been criticized for being better at describing personality than at explaining it, for failing to consider mechanisms that motivate behavior, and for underemphasizing the role of situational factors. Nevertheless, the trait approach—particularly the five-factor model—currently dominates the field of personality.

The Social-Cognitive Approach

The *social-cognitive approach* to personality focuses on the thoughts and feelings that influence people's behavior and assumes that personality is a label that summarizes the unique patterns of thinking and behavior that a person learns in the social world.

Roots of the Social-Cognitive Approach

With roots in research on classical and operant conditioning (including Skinner's *functional analysis* of behavior), the social-cognitive approach has expanded on traditional behavioral approaches by emphasizing the role of cognitive factors, such as observational learning, in personality development.

Prominent Social-Cognitive Theories

Julian Rotter's theory focuses on cognitive expectancies that guide behavior, and it generated interest in assessing general beliefs about whether rewards occur because of personal efforts (internal control) or chance (external control). Albert Bandura believes that personality develops largely through cognitively mediated learning, including observational learning. He regards personality as reciprocally determined by interactions among cognition, environmental stimuli, and behavior. Perceived *self-efficacy*—the belief in one's ability to accomplish a specific task—is an important determinant of behavior. Walter Mischel emphasizes the importance of cognitive person variables and their interactions with the characteristics of particular situations in determining behavior. According to Mischel, we must look at both cognitive person variables and situational variables in order to understand human consistencies and inconsistencies.

Evaluating the Social-Cognitive Approach

The social-cognitive approach has gained wide acceptance because it has merged theories from behavioral and cognitive psychology and used them to explain a wide range of important social behaviors. However, the approach has been criticized for failing both to provide one coherent theory of personality and to capture the complexity, richness, and uniqueness of human personalities.

The Humanistic Psychology Approach

The *humanistic psychology approach* to personality is based on the assumption that people are primarily motivated by a desire to fulfill their natural potential in a uniquely perceived version of reality. So to understand a person, you have to understand the person's view of the world, which serves as the basis for personality and guides behavior.

Prominent Humanistic Theories

Carl Rogers believed that personality development is driven by an innate *actualizing tendency* but also that one's *self-concept* is shaped by social evaluations. He proposed that when people are free from the effects of *conditions of worth*, they are more likely to be psychologically healthy and to achieve self-actualization. Abraham Maslow considered self-actualization as the highest in a hierarchy of needs. Personality development is healthiest, he said, when people have *growth motivation* rather than *deficiency motivation*.

Evaluating the Humanistic Psychology Approach

Although it has an intuitive appeal, the humanistic psychology approach has been faulted for being too idealistic, for failing to explain personality development, for being vague and unscientific, and for underplaying cultural differences in "ideal" personalities.

Assessing Personality

The information used in personality assessment comes from four main sources: life outcomes, situational tests, observer ratings, and self-reports. To be useful, personality assessments must be both reliable and valid.

Projective Personality Measures

Based on psychodynamic theories, *projective personality measures* present ambiguous stimuli in an attempt to tap unconscious personality characteristics. Two popular projective tests are the TAT and the Rorschach Inkblot Test. In general, projective personality measures are less reliable and valid than nonprojective personality measures.

Nonprojective Personality Measures

Nonprojective personality measures contain clearly worded items relating to the individual being assessed; their scores can be compared with group norms. The MMPI and the NEO-PI-R are examples of nonprojective measures.

Personality Tests and Employee Selection

Nonprojective personality measures are often used to identify the people best suited for certain occupations. Although such measures can be helpful in this regard, the people who use them must be aware of the tests' limitations and take care not to violate the rights of test respondents.

LINKAGES TO FURTHER LEARNING

Now that you have finished reading this chapter, how about exploring some of the topics and information that you found most interesting? Here are some places to start.

TALKING POINTS

Here are a few talking points to help you summarize this chapter for family and friends without giving a lecture.

1. We all know someone who seems to have "no personality," but the truth is that everybody has a personality; it is a matter of *what* personality characteristics they have.
2. According to modern versions of Freud's psychodynamic personality theory, our personality characteristics are influenced by the quality of our attachment to caregivers when we were infants.
3. Research in trait theory suggests that everyone's personality can be described in terms of just five main dimensions: openness, conscientiousness, extraversion, agreeableness, and neuroticism.
4. We don't inherit particular personality traits, but we do inherit general temperament, and temperament in childhood provides a reasonably good predictor of adult personality.
5. Humanistic psychology theories of personality suggest that everyone is basically good.
6. According to social-cognitive theories, it is through experiences with other people that we learn the thoughts and actions that become our personality.
7. Personality tests can be useful, but even the best ones cannot provide completely accurate descriptions of individuals or their future behavior.

SUMMARY

Many people pursue what other people consider odd hobbies, such as collecting string, but when does oddness become abnormality? In this chapter, we discuss how society answers that question. We also describe the main types of psychological disorders, their possible causes, their legal status, and how they have been explained over the centuries.

During his first year at college, Mark began to worry about news stories describing the deadly diseases resulting from HIV, the virus that causes AIDS. He took a blood test for HIV and was relieved when it showed no infection. But then he wondered if he might have contracted HIV after he took the test. Internet research revealed that HIV antibodies may not appear until six months after infection. Mark took another blood test, also negative, but he still worried when he learned that the AIDS virus can live outside of the human body for anywhere from ten minutes to several hours or even days.

Given this uncertainty, Mark concluded that HIV can live indefinitely outside of the body and could therefore be anywhere and everywhere. He decided that the only safe course was not just sexual abstinence but absolute cleanliness. Mark began to scrub himself whenever he touched doorknobs, money, walls, floors—anything. People with HIV, he thought, could have touched these things, or they might have bled on the street and he might have tracked their infected blood into his car and house and bathroom. Eventually he felt the need to scrub everything around him up to forty times in each direction; it took him several exhausting hours just to shower and dress. He washed the shower knobs before touching them and, once in the shower, felt that he had to wash his body in cycles of thirteen strokes. If his feet touched the bare floor, he had to wash them again before putting on his underwear to ensure that his feet would not contaminate the fabric. He was sure that his hands, rubbed raw from constant washing, were especially susceptible to infection, so he wore gloves at all times except in the summer, when he wrapped his fingers in bandages. The process of protecting himself from infection was wearing him out and severely restricting his activities; he could not go anywhere without first considering the risk of infection.

Mark suffers from a psychological disorder, also called a *mental disorder* or *psychopathology*. **Psychopathology** is generally defined as patterns of thought, emotion, and behavior that result in personal distress or a significant impairment in a person's social or occupational functioning. Surveys reveal that in any given year in the United States alone, about 26 percent of adults—about 60 million people—display some form of mental disorder and that about half of all Americans can expect to experience a disorder by age 75 (Kessler & Wang, 2008; National Institute of Mental Health [NIMH], 2006; see Figure 15.1). These overall rates of mental disorder are found, with only minor variations, in all segments of U.S. society, including males and females in all ethnic groups and in the young and old. Many of these disorders appear quite early in life. In any given year, about 13 percent of U.S. children display significant mental disorders (Merikangas et al., 2010), and about three-quarters of adult disorders first appear by age 24; half begin as early as 14 (Egan & Asher, 2005; Kessler & Wang, 2008; Twenge et al., 2010).

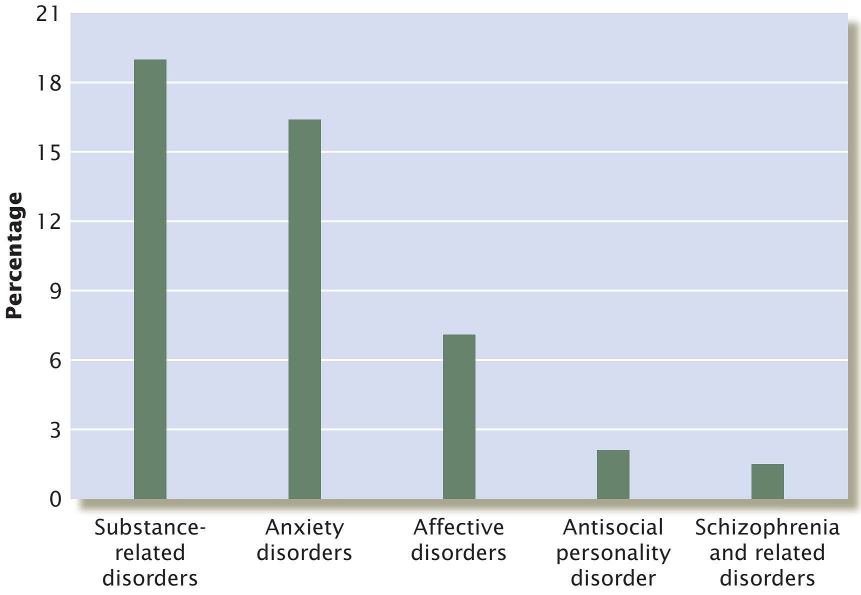
Bear in mind, though, that the prevalence of psychological disorders may be even higher than the percentages just cited. For one thing, major survey studies have examined fewer than half of all known psychological disorders. Further, these studies count each case only once, even though about 45 percent of people

psychopathology Patterns of thinking, feeling, and behaving that are maladaptive, disruptive, or uncomfortable for those who are affected or for those with whom they come in contact.

FIGURE 15.1

Incidence of Specific Psychological Disorders

Several large-scale surveys of adults in the United States revealed that about 26 percent of them experience some form of mental disorder in any given year and that almost half of them have displayed a disorder at some time in life (Kessler & Wang, 2008; National Institute of Mental Health, 2006). Indeed, one survey suggested that only about 20 percent of adults in the U.S. are both free of any form of mental disorder and flourishing (Keyes, 2007). The data shown here summarize the lifetime findings by category of disorder. The same general patterns appear among the more than 400 million people worldwide who suffer from some form of psychological disorder (Kessler & Üstün, 2008; World Health Organization Mental Health Survey Consortium, 2004).



who are diagnosed with one disorder actually display *comorbidity*, meaning that they are diagnosed as having two or even three disorders (Kessler & Wang, 2008; NIMH, 2006).

Psychological disorders are enormously costly in terms of human suffering, wasted potential, and lost resources (e.g., Adler et al., 2006; Insel, 2008; Kessler, Chui, et al., 2008). They are the leading cause of disability in the United States and Canada for people aged 15 to 44 (NIMH, 2006), and a similar pattern appears around the world. Studies have found that psychological disorders ranked second (after cardiovascular disease) in producing disability and shortened life expectancy in industrialized economies (Kessler & Üstün, 2008; World Health Organization Mental Health Survey Consortium, 2004). The impact of these disorders is even greater in less developed countries where treatment is less available (Gureje et al., 2006; Kawakami et al., 2005; Medina-Mora et al., 2005; Miller, 2006; Stewart et al., 2003).

Beyond causing personal suffering and disability, psychological disorders also impose a huge financial burden on families, communities, and society. Expenditures for the diagnosis and treatment of mental disorders increased from $35.2 billion in 1996 to $57.5 billion in 2006—a sharper rise in spending than for heart conditions and cancer (Soni, 2009). Let's consider how these disorders are defined and classified.

Defining Psychological Disorders

A California woman's husband dies, and in her grief, she stays in bed all day, weeping, refusing to eat, at times holding "conversations" with him. In India, a Hindu holy man on a pilgrimage rolls along the ground across 1,000 miles of deserts and mountains, pelted by monsoon rains, until he reaches the sacred place he seeks. In the Middle East, a young man straps explosives to his body and detonates them in a crowded market, killing himself and dozens of others. In London, a British artist randomly scratches parked cars as part of his "creative process." A survey of Swiss adults finds that 18 percent reported having thoughts "that are not my own" (Rössler et al., 2007), and hundreds of people around the world claim to have been abducted by space aliens (Clancy, 2005). These examples and countless others raise the question of where to draw the line between normality and abnormality, between eccentricity, criminality, and mental disorder.

Is This Person Abnormal?

Whether unusual individuals are labeled "abnormal" and perhaps given treatment for psychological disorder depends on a number of factors, including how *abnormality* is defined by the culture in which they live, who is most directly affected by their behavior, and how much distress they suffer or cause.

What Is Abnormal?

The criteria for judging whether people's thinking, emotions, or behaviors are abnormal have been called the "three D's": deviance, distress, and dysfunction. Each criterion has value but also some flaws.

Deviance If we define as *normal* the things most people think and do, an obvious criterion for abnormality is *statistical infrequency*—what is unusual or rare would be considered deviant. By this criterion, the few people who believe that space aliens are stealing their thoughts would be judged abnormal, and the many people who worry about crime or terrorism would not. But statistical infrequency alone is a poor criterion for abnormality because it would define as abnormal any rare quality, including creative genius or world-class athletic ability. Further, the infrequency criterion implies that to be normal, one must conform to all aspects of the majority's standards. Equating nonconformity with abnormality can result in the oppression of those who express unusual or unpopular views or ideas. Finally, just how rare must a behavior be to warrant the designation "abnormal"? The dividing line is not easy to locate.

A related criterion for abnormality is the violation of social norms—the cultural rules that tell us how we should and should not behave in various situations, especially in relation to others (see the chapter on social influence). According to this *norm violation* criterion, people can be described as abnormal if they behave in ways that are unusual or disturbing enough to violate social norms. Like infrequency, though, norm violation alone is an inadequate measure of abnormality. For one thing, some norm violations are better characterized as eccentric or illegal than as abnormal. People who seldom bathe or who stand too close during conversation violate social norms, but are they abnormal or merely annoying? Further, whose norms are we talking about? Social norms vary across cultures, subcultures, and historical eras, so actions that qualify as abnormal in one part of the world might be perfectly acceptable elsewhere.

Distress Another criterion for abnormality is distress, or *personal suffering*. In fact, experiencing distress is the criterion that people often use to decide that their psychological problems are severe enough to require treatment. But personal suffering alone is not an adequate criterion for abnormality. It does not take into account the fact that people are sometimes distressed about characteristics (such as being gay or lesbian) that are not mental disorders. Further, people can display psychological disorders without

Situational Factors in Defining Abnormality

TRY THIS When men in Delhi, India, need a restroom, they can take advantage of outdoor urinals like this one. In some countries, it is even acceptable for men to urinate against buildings on city streets. In the United States and many other places, though, males who urinate anywhere other than the relative privacy of a men's room are considered deviant and might even be arrested for indecent exposure. In other words, situational factors can determine whether a particular behavior is labeled "normal" or "abnormal." Make a list of the reasons you would give for or against calling these men "abnormal." Which criteria for abnormality did you use?

experiencing distress if the disorders have impaired their ability to recognize how maladaptive their behavior is. Those who sexually abuse children, for example, create far more distress in victims and their families than they suffer themselves.

Dysfunction A final criterion for abnormality is *impaired functioning*, which means having difficulty in fulfilling appropriate and expected roles in family, social, and work-related situations (Üstün & Kennedy, 2009). For example, it is normal for people to experience sadness at one time or another, but if their sadness becomes so intense or long-lasting that it interferes with their ability to hold a job or care for their children, it is likely to be considered abnormal. But it isn't quite fair to call someone abnormal just because the person is dysfunctional. The dysfunction might be caused by physical illness, by an overwhelming but temporary family problem, or by a variety of things other than a psychological disorder. Further, some people who display significant psychological disorders are still able to function reasonably well at school, at work, or at home.

Behavior in Context: A Practical Approach

Because no single criterion is entirely adequate for identifying abnormality, mental health practitioners and researchers tend to adopt a *practical approach* that combines aspects of all the criteria we have discussed. They consider the *content* of behavior (what the person does), the sociocultural *context* of the person's behavior, and the *consequences* of the behavior for that person and others.

LINKAGES How do societies define what is abnormal? (a link to Social Influence, p. 730)

Mental health professionals also recognize that the definition of "appropriate," "expected," and "functional" behavior depends to some extent on age, gender, and culture, as well as on the particular situation and the historical era in which people live. For example, a short attention span and unemployment are considered normal in a 2-year-old but inappropriate and problematic in an adult. There are gender-specific norms as well. In some countries, for example, it is more appropriate for women than for men to display emotion. Kisses, tears of happiness, and long embraces are common when women greet each other after a long absence. Men tend to simply shake hands or, at most, hug briefly. Because of cultural differences, hearing a dead relative's voice calling from the afterlife would be more acceptable in certain American Indian tribes than among, say, the families of suburban Toronto. Situational factors are important too. Falling to the floor and speaking an unintelligible language is considered appropriate, even desirable, during the worship services of certain religious groups, but the same behavior would be seen as inappropriate, and a sign of disorder, in a college classroom. Finally, judgments about behavior are shaped by changes in social trends and cultural values. For example, the American Psychiatric Association (APA) once listed homosexuality as a mental disorder but in 1973 dropped this category from its *Diagnostic and Statistical Manual of Mental Disorders.* In taking this step, it was responding to changing views of homosexuality that were prompted in part by the political and educational efforts of gay and lesbian rights groups.

In summary, it is difficult, and probably impossible, to define a specific set of behaviors that everyone, everywhere, will agree constitutes abnormality. The practical approach defines abnormality as patterns of thought, behavior, and emotional reaction that significantly impair people's functioning within their culture (Wakefield, 1992).

Explaining Psychological Disorders

Since the dawn of civilization, people throughout the world have tried to understand the causes of psychological disorder. The earliest explanations of abnormal behavior focused on possession by gods or demons. Disordered people were seen either as innocent victims of spirits or as social or moral deviants suffering supernatural punishment. In Europe during the late Middle Ages, for example, people who displayed threatening or unusual behavior were thought to be controlled by the devil or other evil beings. Supernatural explanations of psychological disorders are still invoked

© J. L. Dugast/Peter Arnold, Inc./Photolibrary

An Exorcism

The exorcism being performed by this Buddhist monk in Thailand is designed to cast out the evil forces believed to be causing this child's disorder. Supernatural explanations of mental disorders remain influential among religious groups in many cultures and subcultures around the world (Fountain, 2000). Awareness of this influence in the United States and Europe has increased recently following cases in which people have died during exorcism rituals (e.g., Christopher, 2003; Radford, 2005).

today in many cultures around the world—including certain ethnic and religious subcultures in North America (Glazer et al., 2004; Legare & Gelman, 2008). Other explanations have focused on mental incompetence, weak character, personal choices, illness or other physical problems, faulty learning, and difficult social conditions.

Different explanations generate differing attitudes and responses toward people who display mental disorders (Fontaine, 2009). In societies where disorder is seen as a sign that a person is evil, that person may be the target of anger and punishment, but where the cause of disorder is thought to be demonic possession, the person may be the object of sympathy and might be offered an exorcism ceremony. If abnormality is viewed as a personal decision to behave in odd ways, those who do so are likely to be avoided, isolated, and ignored, but if psychological problems are assumed to be caused by illness or learned habits, troubled people are likely to be given drugs or offered programs designed to teach less troublesome behaviors.

The Biopsychosocial Approach

Today, most mental health researchers in Western cultures attribute psychopathology to three main causes: biological factors, psychological processes, and sociocultural contexts. For many decades, there was controversy over which of these three causes is most important, but it is now widely agreed that they can all be important. Accordingly, researchers have adopted a **biopsychosocial approach** in which mental disorders are regarded as resulting from the combination and interaction of biological, psychological, and sociocultural factors, each of which contributes in varying degrees to particular problems in particular people (Andrews, 2008; Krueger & Markon, 2006).

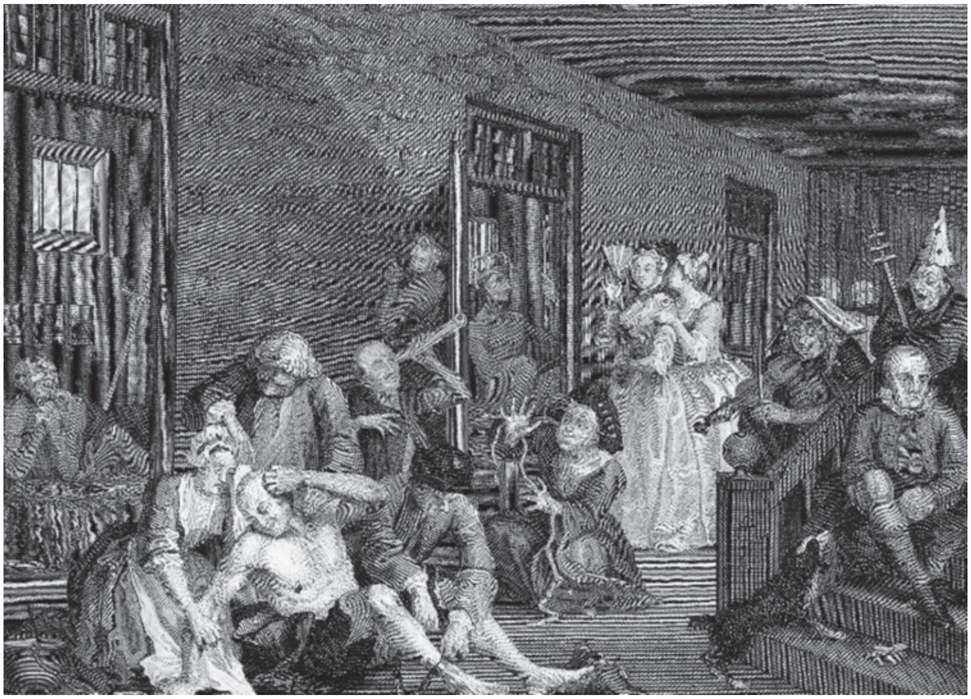
biopsychosocial approach A view of mental disorders as caused by a combination of interacting biological, psychological, and sociocultural factors.

medical model (neurobiological model) A view in which psychological disorders are seen as reflecting disturbances in the anatomy and chemistry of the brain and in other biological processes.

Biological Factors

The biological factors thought to be involved in causing mental disorders include physical illnesses, disruptions or imbalances in bodily processes, and genetic influences. This **medical model** of psychopathology has a long history. For example, the ancient Greek physician Hippocrates said that psychological disorders resulted from imbalances among four *humors,* or bodily fluids (blood, phlegm, black bile, and yellow bile). In ancient Chinese cultures, psychological disorders were thought to result from an imbalance of *yin* and *yang,* the dual forces of the universe flowing in the physical body.

As the medical model gained prominence in Western cultures after the Middle Ages, special hospitals for the insane were established throughout Europe. Treatment



Visiting Bedlam

As shown here in William Hogarth's portrayal of *Bedlam* (slang for London's Saint Mary Bethlehem Hospital), most asylums of the 1700s were little more than prisons. Notice the well-dressed visitors; in those days, people could buy tickets to tour the cells and gawk at the patients.

"The Interior of Bedlam," from *A Rake's Progress* by William Hogarth, 1763

in these early asylums consisted mainly of physical restraints, laxative purges, bleeding of "excess" blood, and induced vomiting. Cold baths, fasts, spinning chairs, and other physical discomforts were also used in efforts to "shock" patients back to normality.

The medical model gave rise to the idea that abnormality is *mental illness,* and in fact, most people in Western cultures today still tend to seek medical doctors and hospitals for the diagnosis and treatment of psychological disorders (Wang et al., 2006). The medical model is now more properly called the **neurobiological model** because it explains psychological disorders in terms of particular disturbances in the anatomy and chemistry of the brain and in other biological processes, including genetic influences (e.g., Kendler, 2005; Plomin & McGuffin, 2003; Williams, 2008). Neuroscientists and others who adopt a neurobiological model study the causes and treatment of these disorders as they would study any physical illness, assuming that problematic symptoms stem primarily from an underlying illness that can be diagnosed, treated, and cured.

Psychological Processes If biological factors are the "hardware" of mental disorders, the "software" is psychological factors, such as our wants, needs, and emotions; our learning experiences; our attachment history; and our way of looking at the world. The roots of this **psychological model** of mental disorders can be seen in ancient Greek literature and drama dealing with the *psyche,* or mind—especially with the mind's struggles to resolve inner conflicts or to overcome the effects of stressful events. These ideas took center stage in the late 1800s when Sigmund Freud challenged the assumption that psychological disorders had only physical causes. As described in the personality chapter, Freud's explanations of mental disorders were part of his *psychodynamic approach.* He believed that those disorders are the result of unresolved, mostly unconscious conflicts that begin in childhood. These conflicts pit people's inborn impulses against the limits placed on those impulses by society.

Other psychological processes can contribute to the development of mental disorders. As described in the personality chapter, *social-cognitive* theorists, also known as *social learning* theorists, see most psychological disorders as resulting from the interaction of past learning and current situations. Just as people learn to avoid hot grills after being burned, say these theorists, bad experiences in school or a dental

psychological model A view in which mental disorder is seen as arising from psychological processes.

LINKAGES Are psychological disorders learned behaviors? (a link to Learning, p. 206)

office can "teach" people to fear such places. Social-cognitive theorists also emphasize that learned expectations, schemas, and other mental processes discussed in the chapter on cognition and language can influence the development of disorders (e.g., Johnson-Laird, Mancini, & Gangemi, 2006). Depression, for example, is seen as stemming from negative events, such as losing a job, but also from the irrational or maladaptive thoughts that people have learned in relation to these events—thoughts such as "I never do anything right."

The *humanistic* approach to personality suggests that behavior disorders appear when a person's natural tendency toward healthy growth is blocked, usually by a failure to be aware of and to express true feelings. When this happens, the person's perceptions of reality become distorted. The greater the distortion, the more serious the psychological disorder.

Sociocultural Context Together, neurobiological and psychological factors go a long way toward explaining many forms of mental disorder. Still, these factors relate mainly to causes residing within the individual. The **sociocultural perspective** suggests that we cannot fully explain all forms of psychopathology without also looking outside the individual—especially at the social and cultural factors that form the background of abnormal behavior. To find causes of disorders in this *sociocultural context,* we must pay attention to **sociocultural factors** such as gender, age, and marital status; the physical, social, and economic situations in which people live; and the cultural values, traditions, and expectations in which they are immersed (Appignanesi, 2009; Lim, 2006; Sue & Sue, 2008). Sociocultural context influences not only what is and is not labeled "abnormal" but also who displays what kind of disorder and how likely people are to receive treatment for it.

Consider gender, for instance. The higher rates of depression among women compared to men may appear partly because many cultures are more tolerant of emotional distress among women than among men (Hightower, 2005; Wupperman & Neumann, 2006). Similarly, the view held in many cultures that excessive alcohol consumption is less appropriate for women than for men is a sociocultural factor that may help explain higher rates of alcohol abuse among men in those cultures (Helzer et al., 1990; Timko, Finney, & Moos, 2005).

Sociocultural factors can influence the overall prevalence of disorders too. For instance, anxiety disorders and depression tend to be less common in China and Japan than in Western countries, including the United States (Lee et al., 2007; Kawakami et al., 2005). And many kinds of psychological disorders increase in frequency among people living in countries ravaged by wars or other stressful conditions (Alhasnawi et al., 2009; Karam et al., 2006).

Sociocultural factors also influence the form that abnormality takes. For example, depression is a *culture-general* disorder, appearing virtually everywhere in the world, but the symptoms that sufferers report tend to differ, depending on cultural background (Falicov, 2003; Hopper & Wanderling, 2000; Whaley & Hall, 2009). In Western cultures, emotional and physical components of disorders are generally viewed separately, so symptoms of depression tend to revolve around despair and other signs of emotional distress. But in China, Japan, and certain other Asian cultures, emotional and physical experiences tend to be viewed as one, so a depressed person is as likely to report stomach or back pain as to complain of sadness (Nakao & Yano, 2006; Weiss et al., 2009).

There are also culture-specific forms of disorder. For instance, Puerto Rican, Guatemalan, Mexican, and Dominican Hispanic women sometimes experience *ataques de nervios* ("attacks of nerves"), a unique way of reacting to stress that includes heart palpitations, shaking, shouting, nervousness, depression, and, on occasion, fainting or seizurelike episodes (Baer, Weller, et al., 2003; Lizardi, Oquendo, & Graver, 2009). In Asia, Khmer refugees sometimes suffer from panic-related fainting spells known as *kyol goeu* (Hinton, Um, & Ba, 2001). And genital retraction syndromes are occasionally observed in a number of places around the world. In Southeast Asia,

sociocultural perspective A way of looking at mental disorders in relation to gender, age, ethnicity, and other social and cultural factors.

sociocultural factors Characteristics or conditions that can influence the appearance and form of maladaptive behavior.

southern China, and Malaysia, men suffering from *koro* fear that their penis will shrivel, retract into the body, and cause death (in females, the fear relates to shriveling of the breasts).

In short, sociocultural factors create differing stressors, social roles, opportunities, experiences, and avenues of expression for different groups of people. They also help shape the disorders and symptoms to which certain categories of people are prone, and they even affect responses to treatment. For example, among people diagnosed with schizophrenia, those living in a developing country such as India are much more likely to improve than those living in a more developed country, such as the United States (Hopper & Wanderling, 2000). We don't yet know for certain what is responsible for this difference, but it may have something to do with the ways in which schizophrenia is understood in different cultures. In the West, schizophrenia is considered a chronic, debilitating, potentially dangerous, long-term illness. As a result, many people diagnosed with schizophrenia find themselves left on the fringes of society. In some non-Western societies, the disorder is seen as less severe and less resistant to treatment. Perhaps this more optimistic view encourages more intense efforts at socialization and, as a result, better outcomes (Mathews, Basily, & Mathews, 2006). Whatever the explanation, these data highlight the fact that any attempt to fully explain psychological disorders must take sociocultural factors into account.

Diathesis-Stress as an Integrative Explanation

The biopsychosocial model is currently the most comprehensive and influential approach to explaining psychological disorders. It is prominent partly because it encompasses so many important causal factors: biological imbalances, genetically inherited characteristics, brain damage, enduring psychological traits, socioculturally influenced learning experiences, stressful life events, and many more.

But how do all these factors interact to actually create disorder? Most researchers believe that inherited characteristics, biological processes, and early learning experiences combine to create a predisposition, or *diathesis* (pronounced "dy-ATH-uh-siss"), for a psychological disorder. Whether or not a person actually develops symptoms of a disorder depends on the nature and amount of stress the person encounters (Elwood et al., 2009; Turner & Lloyd, 2004). For example, a person may have inherited a biological tendency toward depression or may have learned depressing patterns of thinking, but these predispositions may not be expressed as a depressive disorder unless the person is faced with a financial crisis or suffers the loss of a loved one. If such major stressors don't occur, or if the person has adequate skills for coping with them, depressive symptoms may never appear or may be relatively mild (Canli et al., 2006).

This way of thinking about mental disorder is known as the **diathesis-stress model**. It assumes that biological, psychological, and sociocultural factors can predispose us toward a disorder but that it takes a certain amount of stress to actually trigger that disorder. People with a strong diathesis are more vulnerable, so even relatively mild stress may be enough to create a problem. People whose diathesis is weaker may not show signs of a disorder until stress becomes extreme or prolonged. Another way to think about the notion of diathesis-stress is in terms of *risk:* The more risk factors for a disorder a person has—whether in the form of genetic tendencies, personality traits, cultural traditions, or stressful life events—the more likely it is that the person will display a form of psychological disorder associated with those risk factors.

Table 15.1 provides an example of how a particular case of psychopathology might be explained by various biopsychosocial factors and how the case might be summarized in terms of the diathesis-stress model. Later, you'll see how these same factors, and the diathesis-stress model, have been applied to help explain the causes of several other psychological disorders.

diathesis-stress model The notion that psychological disorders arise when a predisposition for a disorder combines with sufficient amounts of stress to trigger symptoms.

TABLE 15.1 The Biopsychosocial Model of Psychopathology

Here are the factors that would be considered by the biopsychosocial approach and combined in the diathesis-stress model to explain the case of José, a 55-year-old electronics technician. A healthy and vigorous father of two adult children, he was forced to take medical leave because of a series of sudden panic attacks in which he experienced dizziness, heart palpitations, sweating, and a sense of impending death. The attacks also kept him from his favorite pastime, scuba diving, but he has been able to maintain a part-time computer business out of his home. (Panic disorder is discussed in more detail later in this chapter; the outcome of this case is described in the chapter on treatment of psychological disorders.)

Explanatory Domain	Possible Contributing Factors
Medical (neurobiological)	José may have organic disorders (e.g., genetic tendency toward anxiety; brain tumor, endocrine dysfunction; neurotransmitter imbalance).
Psychological: psychodynamic	José has unconscious conflicts and desires. Instinctual impulses are breaking through ego defenses into consciousness, causing panic.
Psychological: social-cognitive	José interprets physical stress symptoms as signs of serious illness or impending death. Panic is rewarded by reduction in work stress when he stays home.
Psychological: humanistic	José fails to recognize his genuine feelings about work and his place in life, and he fears expressing himself.
Sociocultural	A culturally based belief that "a man should not show weakness" amplifies the intensity of stress reactions.
Diathesis-stress	José has a biological (possibly genetic) predisposition to be overly responsive to stressors. The stress of work and extra activity exceeds his capacity to cope and triggers panic as a stress response.

Classifying Psychological Disorders

Although definitions of abnormality differ somewhat within and across cultures, there is a set of culture-general and culture-specific behavior patterns that characterize what most mental health professionals consider to be psychopathology. Most of these behavior patterns qualify as disorders because they result in impaired functioning, a main criterion of the practical approach to defining abnormality. It has long been the goal of those who study abnormal behavior to organize these patterns into a system of diagnostic categories.

The main purpose of diagnosing psychological disorders is to determine the nature of people's problems. Once the characteristics of the problems are understood, the most appropriate method of treatment can be chosen. Diagnoses are also important for research on the causes of mental disorders. If researchers can accurately and reliably classify people into particular disorder categories, they will have a better chance of spotting genetic flaws, biological abnormalities, cognitive processes, and environmental experiences that people in the same category might share. Finding that people in a certain diagnostic category share a set of features that differ from those seen in other categories could provide clues about which features are related to the development of each disorder. In short, proper classification can lead to the discovery of causes.

The official North American diagnostic classification system, the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM*), was first published by the American Psychiatric Association in 1952. It contained 168 pages and included sixty-six disorders. Each new edition of the *DSM* has added more categories of disorders. The latest editions, *DSM-IV* and *DSM-IV-TR* (which contains some text revisions), exceed 800 pages and include more than three hundred specific diagnostic labels (American Psychiatric Association, 1994, 2000). Each of these editions was designed to improve the quality of the diagnostic system by taking into account the results of the most recent research on psychopathology.

Outside North America, mental health professionals diagnose mental disorders using the classification systems that appear in the tenth edition of the World Health Organization's *International Classification of Diseases* (*ICD-10*) and its companion volume, the second edition of the *International Classification of Impairments, Disabilities and Handicaps* (*ICIDH-2*). To facilitate international communication and cross-cultural research with respect to psychopathology, *DSM-IV* was designed to be compatible with these manuals, and efforts are under way to remove inconsistencies existing between the systems (Cottler & Grant, 2007; Löwe et al., 2008; Widiger et al., 2006).

A Classification System: *DSM-IV-TR*

DSM-IV-TR describes the abnormal patterns of thinking, emotion, and behavior that define various mental disorders. For each disorder, *DSM* provides specific criteria outlining the conditions that must be present before a person can be given that diagnostic label. Diagnosticians using *DSM-IV-TR* can evaluate troubled people on as many as five dimensions, or *axes* (plural of *axis*). In keeping with the biopsychosocial approach, evaluations on all relevant dimensions are combined to create a broad outline of the person's biological and psychological problems, as well as of any sociocultural factors that might contribute to them. As shown in Table 15.2, major mental disorders, such as schizophrenia or major depressive disorder, are recorded on Axis I. Personality disorders, intellectual disability (previously known as mental retardation), and other lifelong conditions that tend not to change much over time are noted on Axis II. Any medical conditions that might be important in understanding the person's cognitive, emotional, or behavioral problems are listed on Axis III. On Axis IV, the diagnostician notes any psychosocial and environmental factors that are important for understanding the person's psychological problems. These factors include the loss of a loved one, physical or sexual abuse, discrimination, unemployment, poverty, homelessness, inadequate health care, and conflict with religious or cultural traditions. Finally, a rating (from 100 down to 1) of the person's current level of psychological, social, and occupational functioning appears on Axis V. Here is a sample *DSM-IV-TR* diagnosis for a person who received labels on all five axes:

Axis I:	Major depressive disorder, single episode; alcohol abuse.
Axis II:	Dependent personality disorder.
Axis III:	Alcoholic cirrhosis of the liver.
Axis IV:	Problems with primary support group (death of spouse).
Axis V:	Global assessment of functioning: 50.

Notice that the terms *neurosis* and *psychosis* are not included as they once were in *DSM*. They were dropped because they are too vague, but some mental health professionals still sometimes use them as shorthand descriptions. *Neurosis* refers to conditions in which some form of anxiety is the major characteristic. *Psychosis* refers to conditions involving severe thought disorders that leave people "out of touch with reality" or unable to function on a daily basis. The disorders once gathered under these headings now appear in various Axis I categories in *DSM-IV-TR*.

Further changes will appear in a new edition of *DSM, DSM-V,* currently in the final stages of development and slated for publication in 2013. For example, because it is common for certain kinds of disorders, such as anxiety and depression, to appear together, *DSM-V* diagnoses may include some labels that designate "mixed" disorders (Das-Munshi et al., 2008). A variety of other suggestions have been made, such as a new category for disorders characterized primarily by obsessive-compulsive symptoms (Hollander, Braum, & Simeon, 2008; Huprich, 2009). Another proposal is to organize *DSM-V* around symptom clusters or symptom dimensions rather than around specific diagnostic categories (Widiger & Lowe, 2008). The idea behind this *dimensional approach* would be to create a set of symptom "building blocks" that could be combined in many different ways so as to better describe the precise contours of each person's problems. Ratings of the severity of symptoms in each dimension would paint an even more detailed and meaningful picture of the problems a person is experiencing, a picture that would be of more use to clinicians (Krueger & Markon, 2006; Samuel & Widiger, 2006). There are also proposals for *DSM-V* that would label as addictions things such as preoccupation with sex and excessive amounts of eating, shopping, video game playing, texting, e-mailing, and other kinds of Internet use (Young, 2009).

TABLE 15.2 Axes I and II of the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*

Axis I of the fourth edition (*DSM-IV-TR*) lists the major categories of mental disorders. Personality disorders and intellectual disability (mental retardation) are listed on Axis II.

Axis I (Clinical Syndromes)	
1. ***Disorders usually first diagnosed in infancy, childhood, or adolescence.*** Problems such as hyperactivity, childhood fears, conduct disorders, frequent bed-wetting or soiling, and other problems in normal social and behavioral development. Autistic disorder (severe impairment in social, behavioral, and language development), as well as learning disorders.	8. ***Factitious disorders.*** False mental disorders, which are intentionally produced to satisfy some psychological need.
2. ***Delirium, dementia, and amnestic and other cognitive disorders.*** Problems caused by physical deterioration of the brain due to aging, disease, drugs or other chemicals, or other possible unknown causes. These problems can appear as an inability to "think straight" (delirium) or as loss of memory and other intellectual functions (dementia).	9. ***Dissociative disorders.*** Psychologically caused problems of consciousness and self-identification—e.g., loss of memory (amnesia) or the development of more than one identity (dissociative identity disorder, or multiple personality).
3. ***Substance-related disorders.*** Psychological, behavioral, physical, social, or legal problems caused by dependence on or abuse of a variety of chemical substances, including alcohol, heroin, cocaine, amphetamines, painkillers, hallucinogenic drugs, marijuana, and tobacco.	10. ***Sexual and gender identity disorders.*** Problems of (a) finding sexual arousal through unusual objects (such as shoes) or situations (such as exposing one's genitals in public), (b) unsatisfactory sexual activity (sexual dysfunction), or (c) identifying with the opposite gender.
4. ***Schizophrenia and other psychotic disorders.*** Severe conditions characterized by abnormalities in thinking, perception, emotion, movement, and motivation that greatly interfere with daily functioning. Problems involving false beliefs (delusions).	11. ***Eating disorders.*** Problems associated with eating too little (anorexia nervosa) or binge eating followed by self-induced vomiting (bulimia). (See the chapter on motivation and emotion.)
5. ***Affective disorders*** **(also called *mood disorders*)**. Severe disturbances of mood, especially depression, overexcitement (mania), or alternating episodes of each extreme (as in bipolar disorder).	12. ***Sleep disorders.*** Severe problems involving the sleep-wake cycle, especially an inability to sleep well at night or to stay awake during the day. (See the chapter on consciousness.)
6. ***Anxiety disorders.*** Specific fears (phobias); panic attacks; generalized feelings of dread; rituals of thought and action (obsessive-compulsive disorder) aimed at controlling anxiety; and problems caused by traumatic events, such as rape or military combat (see the chapter on health, stress, and coping for more on posttraumatic stress disorder.)	13. ***Impulse control disorders.*** Compulsive gambling, stealing, or fire setting.
7. ***Somatoform disorders.*** Physical symptoms, such as paralysis and blindness, that have no physical cause. Unusual preoccupation with physical health or with nonexistent physical problems (hypochondriasis, somatization disorder, pain disorder).	14. ***Adjustment disorders.*** Failure to adjust to or deal well with such stressors as divorce, financial problems, family discord, or other unhappy life events.
Axis II (Personality Disorders and Intellectual Disability)	
1. ***Personality disorders.*** Diagnostic labels given to individuals who may or may not receive an Axis I diagnosis but who show lifelong behavior patterns that are unsatisfactory to them or that disturb other people. These patterns may involve unusual suspiciousness, unusual ways of thinking, self-centeredness, shyness, overdependency, excessive concern with neatness and detail, or overemotionality, among others.	2. ***Intellectual disability (mental retardation).*** As described in the chapter on cognitive abilities, the label of intellectual disability (previously called mental retardation) is applied to individuals whose measured IQ is less than about 70 *and* who fail to display the skills of daily living, communication, and other tasks expected of people their age.

Not everyone is happy with these proposed changes. Critics, including those involved in the development of *DSM-III*, *DSM-IV*, and *DSM-IV-TR*, are concerned that some of the proposals being considered for *DSM-V* will have unintended negative consequences (Frances, 2009, 2010; Spitzer, 2009). They worry, for example, that giving ratings on many symptom dimensions might make it too easy for people with mild depression or anxiety to be labeled as having an affective or anxiety disorder. Similarly, rating the severity of "symptoms" such as shopping or Internet use—behaviors that are quite common in the general population—could greatly expand the concept of addiction and increase the number of individuals who qualify for a psychiatric diagnosis. These changes, say the skeptics, could create "false epidemics" of mental disorder and result in the "medicalization of normality." The American Psychiatric Association and its *DSM-V* task force defend the changes planned for *DSM-V* as reflecting the best and most current research available in the field of psychopathology (Schatzberg et al., 2009). The final outcome of the debate will not be known for some time.

In the meantime, some researchers have suggested that the diagnosis of behavior disorders should consider not just people's weaknesses and problems but also their character strengths, virtues, prosocial values, and other psychological resources on which they can potentially build during treatment. For example, each problem-oriented *DSM* diagnosis could be supplemented by a list of the strengths (such as resilience, courage, kindness, and tolerance) that contribute to the level of functioning rating that is noted on Axis V. Some researchers have even offered comprehensive lists of human strengths and values from which diagnosticians can choose (Baumgardner & Crothers, 2009; Park, Peterson, & Seligman, 2004; Peterson, 2006b). From the perspective of *positive psychology,* then, diagnosis via the *DSM* alone is regarded as valuable but incomplete. Not only does it tend to ignore people's strengths and values, but it also fails to recognize that people who *lack* certain character strengths and prosocial values can experience or cause a significant amount of discomfort and social impairment, even if they don't meet the "official" criteria for mental disorder.

Anxiety and Depression

People who experience anxiety disorders—particularly panic disorder, generalized anxiety disorder, or posttraumatic stress disorder—are likely to display some other mental disorder as well, most often depression (Byers et al., 2010; Kaufman & Charney, 2000; Roy-Byrne et al., 2000). Accordingly, the next edition of the *DSM* may include a new category, called *mixed anxiety-depression disorder,* to identify people whose symptoms of anxiety and depression combine to impair their daily functioning.

Evaluating the Diagnostic System

Many changes are on the horizon, but how good is the current diagnostic system? One way to evaluate *DSM-IV-TR* is to consider *interrater reliability,* the degree to which different mental health professionals give the same person the same diagnostic label. Reviews of research show that the reliability of *DSM-IV-TR* is acceptable or high for some disorders but not others. For example, interrater agreement is strong on Axis I categories such as anxiety disorders, affective disorders, some childhood disorders, and schizophrenia (e.g., Brown et al., 2001; Jakobsen et al., 2005; Keenan et al., 2007; Simpson et al., 2002). It is much lower, though, for other categories such as somatoform disorders and Axis II personality disorders (Mayou et al., 2005; Shedler & Westen, 2004; Westen, Shedler, & Bradley, 2006; Wollert, 2007). Overall, interrater agreement appears highest overall when diagnosis is based on structured or semistructured interviews that systematically address each area of functioning and provide uniform guidelines for interpreting people's responses (Brown et al., 2001; Rogers, 2003; Widiger & Sanderson, 1995).

Do diagnostic labels carry enough information to accurately describe the people who receive those labels? This *validity* question is difficult to answer because accuracy can be judged in different ways. A diagnosis could be evaluated, for example, on how well it predicts a person's future behavior or perhaps on whether the person is helped by treatment that has helped others in the same diagnostic category. There is certainly evidence for the validity of most *DSM-IV-TR* criteria (Deep-Soboslay et al., 2006; Keenan & Wakschlag, 2004; Kim-Cohen et al., 2005; Langenbucher & Nathan, 2006; Simon & von Korff , 2006; Vieta & Phillips, 2007), but as with reliability, validity is stronger for some diagnoses (e.g., schizophrenia, depression) than for others (e.g., ADHD, somatoform disorders).

In short, the diagnostic system is far from perfect (Beutler & Malik, 2002; Kendell & Jablensky, 2003; Krueger & Markon, 2006; Nestadt et al., 2005; Widiger & Sankis, 2000). First, as already mentioned, people's problems often do not fit neatly into a single category; mixed (or "comorbid") disorders are common. Second, the same symptom (such as sleeplessness) may appear as part of more than one disorder. Third, *DSM-IV-TR* specifies that to be given a particular diagnosis, a person must display a certain number of symptoms at a certain level of severity for a certain period of time. If these criteria are met, a person is said to "have" a certain disorder. But in setting these criteria, the authors of *DSM-IV-TR* had to identify some rather arbitrary boundaries between "having" a disorder and "not having" it. These sharp boundaries fail to capture the varying levels of distress that different people experience. Further, diagnostic criteria often specify that there be "clinically significant impairment," but they provide few, if any, guidelines for what that phrase means. When mental health professionals must decide for themselves whether a particular person's symptoms are severe enough to warrant a particular diagnosis, personal bias can creep into the system (Kim & Ahn, 2002; Widiger & Clark, 2000). All of these factors can lead to misdiagnosis in some cases. Concern over this possibility is especially relevant as the nations of North America and Western Europe become increasingly multicultural. The current *DSM* disorder categories sometimes fail to take into account the ways that different cultures influence the experience and expression of distress. Diagnosticians in these countries are encountering more and more people whose cultural backgrounds they may not fully understand and whose behavior they may misunderstand.

Some people whose behavior differs enough from cultural norms to cause annoyance feel that society should tolerate their "neurodiversity" instead of giving them a diagnostic label (Harmon, 2004). In the same vein, Thomas Szasz (pronounced "sahz") and other critics of the medical model (e.g., Caplan, 1995; Kutchins & Kirk, 1997; Peterson, 2003; Snyder & Lopez, 2006; Szasz, 2003; Wampold, Ahn, & Coleman, 2001) argue that labeling people instead of describing them is dehumanizing because it ignores features that make each person unique. Calling people "schizophrenics" or "alcoholics," Szasz says, may actually encourage the behaviors associated with these labels and undermine the confidence of clients (and therapists) about the chances of improvement.

Obviously, the current system for diagnosing psychological disorders has not satisfied everyone, and it is unlikely that any system ever will. No shorthand diagnostic label can fully describe a person's problems or predict exactly how that person will behave. All that can be reasonably expected of a diagnostic system is that it be based on the latest research on psychopathology and that it provide informative, general descriptions of the types of problems displayed by people who have been placed in various categories.

THINKING **CRITICALLY**

Is Psychological Diagnosis Biased?

Some researchers and clinicians worry that problems with the reliability and validity of the diagnostic system are due partly to bias in its construction and use. They point out, for example, that if the diagnostic criteria for various disorders are based on research that focused on one culture, one gender, one ethnic group, or one age group, those criteria might not apply to other groups. Moreover, because diagnosticians, like other people, hold expectations and make assumptions about males versus females and about individuals from differing cultures or ethnic groups, those cognitive biases could color their judgments. This "prejudging" process could lead to the application of diagnostic criteria in ways that are slightly but significantly different from one case to the next.

What am I being asked to believe or accept?

Here we focus on ethnicity as a possible source of bias in diagnosing psychopathology. It is of special interest because there is evidence that like social class and gender, ethnicity is an important sociocultural factor in the development of mental disorder. So the assertion to be considered is that clinicians in the United States base their diagnoses partly on clients' ethnic background and, more specifically, that there is bias in diagnosing African Americans.

What evidence is available to support the assertion?

Several facts suggest the possibility of ethnic bias in psychological diagnosis. For one thing, African Americans receive the diagnosis of schizophrenia more frequently than European Americans do (American Psychiatric Association, 2000; Barnes, 2004; Kilbourne et al., 2004; Minsky et al., 2003). In fact, certain kinds of odd symptoms tend to be diagnosed as an affective disorder in European Americans but as schizophrenia in African Americans (Neighbors et al., 2003; Schwartz & Feisthamel, 2009). Further, relative to their presence in the general population, African Americans are overrepresented in public mental hospitals, where the most serious forms of disorder are seen, and underrepresented in private hospitals and outpatient clinics, where less severe problems are treated (Barnes, 2004; Snowden & Cheung, 1990; U.S. Surgeon General, 1999). African Americans are also more likely than European Americans to be discharged from mental hospitals without a definitive diagnosis, suggesting that clinicians have more difficulty diagnosing their disorders (Sohler & Bromet, 2003). Other research suggests that emergency room physicians are less likely to recognize psychiatric disorders in African American patients than in patients from other groups (Kunen et al., 2005).

There is also evidence that African Americans and members of other ethnic minority groups are underrepresented in research on mental disorders. One review found that minority participants were included in less than 30 percent of the research published in five leading clinical psychology journals over a seventeen-year period (Iwamasa, Sorocco, & Koonce, 2002). If such underrepresentation leaves clinicians less sensitive to the operation of sociocultural factors in certain groups, the quality of their diagnoses could be affected. For example, a European American diagnostician might interpret an African American patient's suspiciousness as evidence of paranoid thinking when it might actually reflect the patient's history of unpleasant experiences with white authority figures (Whaley, 2001).

Are there alternative ways of interpreting the evidence?

Differences among ethnic groups in diagnosis or treatment do not automatically indicate bias based on ethnicity. Perhaps there are real differences in psychological functioning across different ethnic groups. If, relative to other groups, African Americans are exposed to more risk factors for disorder, such as poverty, violence, or other major stressors, they could be more vulnerable to more serious forms of mental disorder (Plant & Sachs-Ericsson, 2004; Turner & Lloyd, 2004). And poverty, not diagnostic bias, could be responsible for the fact that African Americans more often seek help at less expensive public hospitals than at more expensive private ones. Indeed, African Americans are more likely than European Americans to bring mental health problems to hospital emergency rooms rather than to family physicians or other mental health service providers. So perhaps African Americans are less likely to come to the attention of mental health professionals until their disorders have become more severe (Nelson, 2006).

What additional evidence would help evaluate the alternatives?

So do African Americans actually display more signs of schizophrenia, or do diagnosticians just perceive them as more disordered? One way of approaching this question is to conduct experiments in which diagnosticians assign labels to clients on the basis of case histories, test scores, and the like. In some studies, the cases are selected so that pairs of clients show about the same degree of disorder but one member of the pair is identified as European American and the other as African American. In other studies, the same case materials, identified as representing either African American or European American patients, are presented to different diagnosticians. Bias in diagnosis would be suggested if, for example, patients identified as African American were labeled as more seriously disordered than others.

The results of such studies are mixed. Most have found little or no ethnic bias (e.g., Angold et al., 2002; Garb, 1997; Kales et al., 2005a, 2005b; Littlewood, 1992), but because the diagnosticians could have been aware of the purpose of the research, they might have gone out of their way to be unbiased (Abreu, 1999). Some evidence of diagnostic bias against African Americans *has* been found when clinicians were unaware of the purpose of the research (e.g., Baskin, Bluestone, & Nelson, 1981; Jones, 1982). But bias can result in underdiagnosis as well as overdiagnosis. One review of research found that African American children exhibited more signs of hyperactivity disorder than

European American children did but were given that diagnosis less often (Miller, Nigg, & Miller, 2009). In another study, socially disruptive African American youngsters were less likely than disruptive European American adolescents to be diagnosed with conduct disorder (Pottick et al., 2007). These results suggest that some diagnosticians may believe that a certain amount of overactivity, inattention, and misbehavior is to be expected of African Americans and that this behavior is therefore "normal" for them.

Bias has also appeared in studies aimed at identifying the factors influencing clinicians' diagnostic judgments following extensive interviews with patients. One study conducted in a hospital setting found that in arriving at a diagnosis, psychiatrists were more likely to see hallucinations and paranoid thinking in African American patients than in patients who were not African American. Symptoms of affective disorders were more likely to be seen in those who were not African American (Trierweiler et al., 2000). As noted earlier, these differences could reflect differences in the rate of disorder in different populations, but when people were interviewed in their own homes as part of large-scale mental health surveys, the diagnosis of schizophrenia was given only slightly more often to African Americans than to European Americans (Robins & Regier, 1991; Snowden & Cheung, 1990). In other words, ethnic bias is suggested, at least for some diagnoses, for patients who are evaluated in mental hospitals (Trierweiler et al., 2000, 2005).

What conclusions are most reasonable?

Just as *DSM-IV-TR* is imperfect, so are the people who use it. As described in the chapters on cognition and language and on social cognition, biases and stereotypes affect human thinking to some extent in virtually every social situation. It should not be surprising, then, that they operate in diagnosis as well. But diagnostic bias does not necessarily reflect deliberate discrimination. Like the processes of prejudice discussed in the chapter on social cognition, diagnostic bias based on ethnicity can operate unconsciously, without the diagnostician's awareness (Abreu, 1999; Boysen, 2009). So no matter how precisely researchers specify the criteria for assigning diagnostic labels, conscious or unconscious cognitive biases and stereotypes are likely to threaten the objectivity of the diagnostic process (Poland & Caplan, 2004; Trierweiler et al., 2000). Still, it would be incorrect to conclude that the entire diagnostic system is biased against African Americans because there is evidence that given the same symptom information, clinicians are just as likely to assign certain diagnoses, such as depression, to African Americans as to European Americans (Kales et al., 2005a, 2005b).

To minimize the bias that does operate, it has been suggested that diagnosticians should focus more intently than ever on the fact that their concepts of "normality" and "abnormality" are affected by sociocultural values that they may not share with a given client (Kales et al., 2006; Landrine, 1991; Whaley & Hall, 2009). They must also become more aware that the cognitive shortcuts and biases that affect everyone else's thinking and decision making can impair their own clinical judgments (Lopez, 1989). Perhaps the best way to counteract clinicians' cognitive shortcomings is to teach them to base their diagnoses solely on published diagnostic criteria, standardized interview formats, and statistically validated decision rules (aided, perhaps, by specialized computer programs) rather than relying on their potentially biased clinical impressions (Akin & Turner, 2006; Bernstein, Kramer, & Phares, 2009).

We don't have the space to cover all the *DSM-IV-TR* categories, so we will sample several of the most prevalent and socially significant ones. As you read, try not to catch "medical student's disease." Just as medical students often think they have the symptoms of every illness they read about, some psychology students worry that their behavior (or that of a relative or friend) signals a mental disorder. These days, this worry is called *cyberchondria* (Harding et al., 2008; Lewis, 2006; Markoff, 2008) because it often stems from people's unguided use of the Internet to learn about psychiatric disorders (Al-Shammary et al., 2007; Lewis, 2006; Trotter & Morgan, 2008).

Just remember that everyone has problems sometimes. Before deciding that you or someone you know needs psychological help, consider whether the content, context, and functional impairment associated with the behavior would qualify it as abnormal according to the criteria of the practical approach.

Anxiety Disorders

© Louie Psihoyos/Corbis

It's a Long Way Down

Almost everyone is afraid of something, but about 9 or 10 percent of U.S. adults have a specific phobia in which fear interferes significantly with daily life (Kessler & Wang, 2008). For example, people with acrophobia (fear of heights) would not do well in a job that requires being in this high position.

If you have ever been tense before an exam, a date, or a job interview, you have some idea of what anxiety feels like. Increased heart rate, sweating, rapid breathing, a dry mouth, and a sense of dread are common features of anxiety. Brief episodes of moderate anxiety are a normal part of life for most people. But when anxiety is so intense and long-lasting that it impairs a person's daily functioning, it is called an **anxiety disorder** (Kessler & Wang, 2008).

Types of Anxiety Disorders

Here we discuss four types of anxiety disorders: *phobia, generalized anxiety disorder, panic disorder,* and *obsessive-compulsive disorder.* Another type, called posttraumatic stress disorder, is described in the chapter on health, stress, and coping. Together, these are the most common psychological disorders in North America; about 29 percent of the U.S. population will have an anxiety disorder at some point in their lives (Kessler et al., 2009).

Phobia An intense, irrational fear of an object or situation that is not likely to be dangerous is called a **phobia**. People who experience phobias usually realize that their fears are groundless, but that's not enough to make the anxiety go away. The continuing discomfort and avoidance of the object or event may greatly interfere with daily life. Thousands of phobias have been described; Table 15.3 lists just a few.

DSM-IV-TR classifies phobias into specific, social, and agoraphobia subtypes. **Specific phobias** include fear and avoidance of heights, blood, animals, automobile or air travel, or other specific stimuli and situations. In the United States and other developed nations, they are the most prevalent of the anxiety disorders, affecting 9 to 10 percent of adults and children (Hollander & Simeon, 2008; Kessler & Wang, 2008; NIMH, 2006). Here is an example:

> Mr. L. was a 50-year-old office worker who became terrified whenever he had to drive over a bridge. For years, he avoided bridges by taking roundabout ways to and from work, and he refused to be a passenger in other people's cars, just in case they might use a bridge. Even this very inconvenient adjustment failed when Mr. L. was transferred to a position requiring frequent automobile trips, many of which were over bridges. He refused the transfer and lost his job.

TABLE 15.3 Some Phobias

Phobia, the Greek word for "morbid fear," refers to *Phobos*, the Greek god of terror. The names of most phobias begin with the Greek word for the feared object or situation.

Name	Feared Stimulus	Name	Feared Stimulus
Acrophobia	Heights	Aerophobia	Flying
Claustrophobia	Enclosed places	Entomophobia	Insects
Hematophobia	Blood	Gamophobia	Marriage
Gephyrophobia	Crossing a bridge	Ophidiphobia	Snakes
Kenophobia	Empty rooms	Xenophobia	Strangers
Cynophobia	Dogs	Melissophobia	Bees

anxiety disorder A condition in which intense feelings of apprehension are longstanding and disruptive.

phobia An anxiety disorder involving strong, irrational fear of an object or situation that does not objectively justify such a reaction.

specific phobia An anxiety disorder involving fear and avoidance of heights, animals, or other specific stimuli and situations.

Social phobias involve anxiety about being criticized by others or acting in a way that is embarrassing or humiliating. The anxiety is so intense and persistent that it impairs the person's normal functioning. Common social phobias are fear of public speaking or performance ("stage fright"), fear of eating in front of others, and fear of using public restrooms (Gren-Landell et al., 2009; Kleinknecht, 2000).

Generalized social phobia is a more severe form in which fear occurs in virtually all social situations (Jacobs et al., 2009; Mineka & Zinbarg, 2006). One person described the problem this way (NIMH, 2007, p. 9):

> In any situation, I felt fear. I would be anxious before I even left the house, and it would escalate as I got closer to a college class, a party, or whatever. When I would walk into a room full of people, I'd turn red, and it would feel like everybody's eyes were on me. . . . I couldn't think of anything to say; . . . I couldn't wait to get out.

Sociocultural factors can alter the nature of social phobias. For example, in Japan, where cultural training emphasizes group-oriented values and goals, a common social phobia is *taijin kyofusho,* the fear that your appearance, odor, or actions are causing offense or embarrassment to those around you (Kleinknecht, 1994).

Agoraphobia is a strong fear of being away from a safe place, such as home; of being away from a familiar person, such as a spouse or close friend; or of being in a place (such as a crowded theater or mall) that might be difficult to leave or where help may be unavailable. These fears can cause serious problems. People who suffer from agoraphobia typically avoid social situations and refuse to shop, drive, or use public transportation. They may be unable to work and can easily become isolated. In severe cases, agoraphobia can make leaving home such a frightening prospect that people become housebound, unwilling to even try going out alone. Most individuals who display agoraphobia have a history of panic attacks, which we describe later (Fava et al., 2008). Their intense fear of public places occurs partly because they don't want to risk triggering an attack by going to places in which they had a previous attack or where they feel an attack would be dangerous or embarrassing (Kessler, Chiu, et al., 2006).

Like other phobias in Western cultures, agoraphobia is more often reported by women (McLean & Anderson, 2009). However, in other cultures, such as India, where being a housebound woman is considered less unusual than in the United States, individuals diagnosed as agoraphobic tend to be male (Raguram & Bhide, 1985). Agoraphobia is far less common than specific phobias (affecting about 0.8 percent of the U.S. population, versus 9 percent for specific phobias), but it often leads people to seek treatment, mainly because it interferes so severely with everyday life (Kessler & Wang, 2008).

Generalized Anxiety Disorder

Excessive and long-lasting anxiety that is not focused on any particular object or situation marks **generalized anxiety disorder (GAD)**. Because the problem occurs in almost all situations and because the person cannot pinpoint its source, this type of anxiety is sometimes called *free-floating anxiety* and is essentially a disorder of worry (Fisher & Wells, 2009). For weeks at a time, the person feels anxious and worried, sure that some disaster is about to happen. The person becomes jumpy and irritable; sound sleep is impossible. Fatigue, inability to concentrate, and physiological signs of anxiety are also common. Generalized anxiety disorder affects about 3 percent of the U.S. population in any given year and about 6 percent of the population at some point in their lives (Hollander & Simeon, 2008; Kessler & Wang, 2008). This disorder tends to appear somewhat later in life than most of the other anxiety disorders (the median age of onset is 31 for GAD, whereas it is the teens or early twenties for phobias). Generalized anxiety disorder is more common in women, often accompanying other problems such as depression or substance abuse (Wittchen & Hoyer, 2001).

social phobia An anxiety disorder involving strong, irrational fears relating to social situations.

agoraphobia An anxiety disorder involving strong fear of being alone or away from the security of home.

generalized anxiety disorder (GAD) A condition that involves relatively mild but long-lasting anxiety that is not focused on any particular object or situation.

Panic Disorder For some individuals, anxiety takes the form of **panic disorder**. Like the man profiled in Table 15.1, people suffering from panic disorder experience recurrent, terrifying *panic attacks* that come without warning or obvious cause. These attacks are marked by intense heart palpitations, pressure or pain in the chest, dizziness or unsteadiness, sweating, and feeling faint. Often victims believe they are having a heart attack. Their overall quality of life suffers because they worry constantly about suffering future panic episodes and consequently restrict their activities to avoid possible embarrassment (Kinley et al., 2009). As noted earlier, fear of experiencing panic attacks while alone or away from home can lead to agoraphobia, as it does in about one-third of people with panic disorder (Carter & Barlow, 1995; NIMH, 2006; Robins & Regier, 1991). Panic disorder can continue for years, with periods of improvement followed by recurrences (Ehlers, 1995). Many people have experienced at least one panic attack in their lives, but only about 2 to 3 percent of the adult population develops full-blown panic disorder in any given year (American Psychiatric Association, 2000; Kessler & Wang, 2008; Kessler, Chiu, et al., 2006). Here is one example:

> Geri, a 32-year-old nurse, had her first panic attack while driving on a freeway. Afterward, she would not drive on freeways. Her next attack occurred while with a patient and a doctor in a small examining room. A sense of impending doom flooded over her, and she burst out of the office and into the parking lot, where she felt immediate relief. From then on, fear of another attack made it impossible for her to tolerate any close quarters, including crowded shopping malls. She eventually quit her job because of terror of the examining rooms.

Obsessive-Compulsive Disorder Anxiety is also at the root of **obsessive-compulsive disorder (OCD)**, which affects about 1 percent of the population in any given year in the United States and elsewhere (Kessler & Wang, 2008; Ruscio et al., 2010). This disorder is equally common in males and females (Zhang et al., 2009), and like Mark, whose story opened this chapter, people displaying OCD are plagued by persistent, upsetting, and unwanted thoughts—called **obsessions**—that often center on the possibility of infection, contamination, or doing harm to themselves or others. They do not actually carry out harmful acts, but the obsessive thoughts motivate ritualistic, repetitive behaviors—called **compulsions**—that are performed in an effort to avoid some dreaded outcome or to reduce feelings of anxiety associated with the obsessions (Noyes & Hoehn-Saric, 2006). For example, Mark engaged in incessant, ritualized cleaning to protect himself from infection. Other common compulsions include rituals such as checking locks; repeating words, images, or numbers; counting things; or arranging objects "just so." Obsessions and compulsions are much more intense than the familiar experience of having a repetitive thought or tune "in the back of your mind" or rechecking that a door is locked. In OCD, the obsessions and compulsions are intense, disturbing intrusions that can severely impair daily activities (Morillo, Belloch, & Garcia-Soriano, 2007). Although many people who display this disorder recognize that their thoughts and actions are irrational, they still experience severe agitation and anxiety if they try to interrupt their obsessions or give up their compulsive behaviors.

A Cleaning Compulsion

Mild obsessions are relatively common (Fullana et al., 2009), but obsessive-compulsive disorder is diagnosed when a culturally expected degree of cleanliness becomes an obsessive preoccupation with germs and a disruptive compulsion to clean things. Though learning experiences and stress appear to play the major role in shaping and triggering this and other anxiety disorders, biological factors, including genetically inherited characteristics and problems in certain neurotransmitter systems in the brain, may result in an oversensitive nervous system and a predisposition toward anxiety.

Causes of Anxiety Disorders

As with all the forms of psychopathology we will consider, the exact causes of anxiety disorders are a matter of some debate. However, there is good evidence that biological, psychological, and social factors all contribute. Biological predispositions, distortions in thinking, and certain learning experiences appear to be particularly important (Coelho & Purkis, 2009; Williams et al., 2005). The exact nature and combination of causal factors varies from one anxiety disorder to the next. For example, the brain regions involved in panic disorder are not identical to those involved in obsessive-compulsive disorder, and the learning experiences contributing to specific phobia may differ from those contributing to agoraphobia.

Biological Factors Most anxiety disorders, including panic disorder, obsessive-compulsive disorder, and generalized social phobia, appear to run in families (Bolton et al., 2006; Grabe et al., 2006; Stewart et al., 2007). This tendency may be partly due to environmental factors that affect members of the same family, but it also suggests that people may inherit a predisposition to develop anxiety disorders (e.g., Fyer et al., 2006). Genetic influences on these disorders are suggested by research showing that if one identical twin has an anxiety disorder, the other twin (who shares the same genes) is more likely also to have an anxiety disorder than is the case in nonidentical twin pairs (Bolton et al., 2006; Kendler et al., 2002). Data from twin, family, and other studies suggest, for example, that genetic influences play a relatively strong role in panic disorder and generalized anxiety disorder, particularly when there is early onset of symptoms (Bolton et al., 2006; Hettema, Neale, & Kendler, 2001; Neumeister et al., 2004). Some evidence suggests that genetic factors appear to influence social phobia more strongly in males than in females (Kendler et al., 2002), but overall, the genetic and environmental risk factors for anxiety disorders are similar in men and women (Hettema et al., 2005).

Some inherited predispositions may be rather specific. For instance, one study has found that identical twins were more likely than other siblings to share phobias of small animals and social situations but not a fear of heights or enclosed spaces (Skre et al., 2000). The degree of genetic influence in anxiety disorders is moderate, however (Hollander & Simeon, 2008), and varies among disorders. For instance, genes appear to play a stronger role in early-onset panic disorder and generalized anxiety disorder than in specific phobias (Bolton et al., 2006; Distel et al., 2008; Neumeister et al., 2004). Researchers are trying to identify the specific genes or gene combinations involved in anxiety disorders. For example, a number of genes have been suggested as contributing to OCD, including two variations of the SLlC6A4 gene (Saiz et al., 2008). This work is difficult, though, because the mere presence of a gene doesn't necessary predict the appearance of a disorder. Rather, as described in our discussion of *epigenetics* in the opening chapter of this book, genes are often "switched on" or "switched off" by environmental triggers (Uddin et al., 2010).

It will take much more research to determine the degree to which various anxiety disorders are influenced by specific genetic factors or more general ones. For example, as described in the personality chapter, people who display anxiety disorders may have inherited an autonomic nervous system that is oversensitive to stress and easily conditioned, thus predisposing them to react with intense anxiety to a wide range of situations (Akimova, Lanzenberger, & Kasper, 2009; Bracha, 2006; Naragon-Gainey, 2010; Nash et al., 2008). A predisposition for developing anxiety disorders may also stem from abnormalities in the brain's neurotransmitter activity. Excessive activity of norepinephrine circuits in certain parts of the brain has been linked with panic disorder, and dysregulation of serotonin has been associated with obsessive-compulsive disorder and social phobia (Lanzenberger et al., 2007). Supporting this view is evidence that medications that affect these neurotransmitters are often effective in the treatment of OCD and other anxiety disorders (Bartz & Hollander, 2006).

Psychological and Environmental Factors Although biological predispositions may set the stage for anxiety disorders, most researchers agree that environmental stressors and psychological factors, including cognitive processes and learning, are crucial to the development of most anxiety disorders (Hudson & Rapee, 2009; Mineka & Zinbarg, 2006; Moses & Barlow, 2006; Wilcox et al., 2008). To see the effects of environmental stressors, one need only look at the dramatic rise in cases of posttraumatic stress disorder following military combat, natural disasters, or terrorist attacks (Galea, Resnick, et al., 2002; Hoven et al., 2005). The impact of learning can be seen in families in which parents don't socialize much, tend to be suspicious of others, and constantly exaggerate life's everyday dangers. These parents may unwittingly promote social anxiety in their children—especially children born with a tendency toward shyness—by influencing them to interpret social situations as threatening

panic disorder An anxiety disorder involving sudden panic attacks.

obsessive-compulsive disorder (OCD) An anxiety disorder involving repetitive thoughts and urges to perform certain rituals.

obsessions Persistent, upsetting, and unwanted thoughts that interfere with daily life and may lead to compulsions.

compulsions Repetitive behaviors that interfere with daily functioning but are performed in an effort to prevent dangers or events associated with obsessions.

(Essex et al., 2010). Abuse or other traumatic childhood experiences also increase the risk of developing an anxiety disorder, particularly panic disorder (Brook & Schmidt, 2008; Safren et al., 2002).

People with an anxiety disorder often exaggerate the dangers in their environment, thereby creating an unrealistic expectation that bad events are going to happen (Brook & Schmidt, 2008; Cisler & Koster, 2010; Ouimet, Gawronski, & Dozois, 2009). This expectation leads them to dwell on and be constantly on the lookout for negative events (Vroling & de Jong, 2010; Wells & Matthews, 2006; Wong & Moulds, 2009). Further, because they tend to underestimate their capacity to control threatening events, they are likely to experience anxiety and desperation if and when feared events do occur. Their lack of perceived control can in turn lead these people to overreact to threatening situations or avoid them entirely (Wells & Matthews, 2006; White et al., 2006). Consider the development of a panic attack. Unexplained symptoms of physical arousal may set the stage for a panic attack, but it is the person's sensitivity to and cognitive interpretation of those symptoms that can determine whether or not the attack actually develops (Domschke et al., 2010; Hollander & Simeon, 2008; Lim & Kim, 2005). In fact, panic attacks are less likely in panic disorder patients who believe they can control the source of their discomfort (Rapee et al., 1992; White et al., 2006). In short, a number of dysfunctional beliefs and cognitive distortions are associated with the development of anxiety disorders (Kolassa et al., 2009; Purdon, 2009).

LINKAGES

Anxiety Disorders and Learning

LINKAGES Can we learn to become "abnormal?" (a link to Learning, p. 206)

The principles discussed in the chapter on learning also play an important role in anxiety disorders. For example, distressing thoughts—about money or illness, for example—often give rise to anxiety and worry, especially when people are already under stress or feel incapable of dealing with their problems. As the thoughts become more persistent, anxiety increases. If doing something such as, say, cleaning the kitchen temporarily relieves the anxiety, that behavior may be strengthened through the process of negative reinforcement discussed in the chapter on learning. But cleaning can't eliminate the obsessive thoughts, so they return, and the actions become compulsive, endlessly repeated rituals that keep the person trapped in a vicious circle

Learning by Watching

Many phobias, including those involving needles, blood, and medical-related situations, are acquired vicariously—by what we see and hear. In fact, fear developed through observational learning can be as strong as fear developed through direct experience. Fearlessness can also be learned vicariously. By simply watching the boy in the dental chair as he learns to relax with his dentist, the other youngster is less likely to be distressed when it is his turn.

of anxiety. To social-cognitive theorists, then, obsessive-compulsive disorder is a pattern that is sparked by distressing thoughts and maintained by operant conditioning (Abramowitz et al., 2006).

Phobias, too, may be partly based on learning, especially on the principles of classical conditioning and observational learning described in the learning chapter. The feared object becomes an aversive conditioned stimulus after being associated with a traumatic event that acts as an unconditioned stimulus (Olatunji, 2006; Stein, 2006). Fear of dogs, for example, may result from a dog attack. But fear can also be learned merely by seeing or hearing about other people's bad experiences. These fears can even be learned by watching TV or movies (Askew, Kessock-Philip, & Field, 2008; Cook & Mineka, 1990). Perhaps you know someone who became reluctant to take a shower after seeing the horrific murder scene in Alfred Hitchcock's film *Psycho*. Once phobias are learned, avoiding the feared object or situation prevents the person from finding out that there is nothing to fear. This cycle of avoidance helps explain why many phobias do not simply extinguish, or disappear, on their own (Lovibond et al., 2009).

Why are phobias about snakes and spiders so common, even though people are seldom harmed by them? And why are there so few phobias about electrical shock, even though lots of people receive accidental shocks? As discussed in the chapter on learning, the answer may be that we are *biologically prepared* to learn associations between certain stimuli and certain responses. These stimuli and responses, then, would be especially easy to link through conditioning. Specifically, we may be biologically prepared to learn to fear and avoid stimuli that harmed our evolutionary ancestors (Canu, 2008; Öhman & Mineka, 2001, 2003; Skre et al., 2000).

The notion that people are biologically prepared to learn certain phobias is supported by laboratory evidence. For example, a group of Swedish psychologists attempted to condition people to fear certain stimuli by associating those stimuli with electrical shocks (Öhman, Dimberg, & Öst, 1985). The research participants developed approximately equal conditioned anxiety reactions to photos of houses, human faces, and snakes. Later, however, when they were tested without shock, their fear reaction to snakes remained long after their reaction to houses and faces had faded. A series of investigations with animals has also supported preparedness theory (Cook & Mineka, 1990; Shibasaki & Kawai, 2009). If a monkey sees

Biological Preparedness

TRY THIS Being predisposed to learn to fear snakes and other potentially dangerous stimuli makes evolutionary sense. Humans and other animals who rapidly learn a fear response to objects or situations that they see frightening their parents or peers are more likely to survive to pass on their genes to the next generation. Are there things that you are especially afraid of? If so, list them, and make a note of how you think these fears developed. How many of them appear to have "survival value"?

another monkey behaving fearfully in the presence of a snake, it quickly develops a strong and persistent fear of snakes. However, if the snake is entwined in flowers, the observer monkeys come to fear only the snake, not the flowers. So the fear conditioning appears to be selective, focusing only on potentially dangerous creatures such as snakes or crocodiles (Mühlberger et al., 2006; Zinbarg & Mineka, 1991) and not on harmless objects.

Learning is obviously important in the development of fear, but learning principles alone cannot explain why exposure to certain stimuli causes anxiety disorders in some people and not in others (Field, 2006). Leyro, Zvolensky, & Bernstein; Why is it, for example, that some survivors of the 9/11 terrorist attacks developed phobias or posttraumatic stress disorder and others did not? As suggested by the diathesis-stress approach and as discussed in the chapter on health, stress, and coping, the impact of people's experiences is heightened or dampened by other factors, such as their genetic and biological vulnerability or resilience to stress, their previous experiences with frightening events, their expectations and other cognitive habits, and the social support and other conditions that follow the trauma (Armfield, 2006; Leyro, Zvolensky, & Bernstein, 2010; Mineka & Zinbarg, 2006; Xie et al., 2009). In short, learning—including the learning that supports the development of anxiety disorders—occurs more quickly among those who are biologically and psychologically prepared for it.

Somatoform Disorders

A 10-year-old boy was hospitalized with what appeared to be a case of juvenile myasthenia gravis (a weakening of the voluntary muscles). For five weeks he had been unable to open his eyes, which had prevented him from going to school. Physical examination revealed no other abnormalities, but he was the star of his school's football team, and his symptoms first appeared on the day that he had been blamed for the team's defeat (Leary, 2003). Sometimes people show symptoms of a *somatic,* or bodily, disorder, even though it has no physical cause. Because these conditions reflect psychological problems that take somatic form, they are called **somatoform disorders**. The classic example is **conversion disorder**, a condition in which a person appears to be, but is not, blind, deaf, paralyzed, or insensitive to pain in various parts of the body. (An earlier term for this disorder was *hysteria*.) Conversion disorders are rare, accounting for only about 2 percent of diagnoses (American Psychiatric Association, 2000; Eifert, Zvolensky, & Louis, 2008). Although they can occur at any point in life, they usually appear in adolescence or early adulthood.

Conversion disorders differ from true physical disabilities in several ways. First, they tend to appear when a person is under severe stress. Second, they often help reduce that stress by allowing the person to avoid unpleasant or threatening situations. Third, the person may show remarkably little concern about what is apparently a rather serious problem. Finally, the symptoms may be neurologically impossible or improbable, as Figure 15.2 illustrates.

Can people who display a conversion disorder actually see, hear, or move, even though they act as if they cannot? Observations and experiments suggest that they can. Supposedly paralyzed people have been seen to sleepwalk, and supposedly blind or deaf people make use of sights and sounds to guide their behavior (e.g., Blake, 1998; Grosz & Zimmerman, 1970). But this does not mean that they are *malingering,* or faking. In fact, conversion disorder is diagnosed only when the symptoms are *not* being faked. Rather than destroying sensory or motor ability, the conversion process may prevent the person from being aware of information that the brain is processing (Ballmaier & Schmidt, 2005; Harvey, Stanton, & David, 2006).

Another somatoform disorder is **hypochondriasis** (pronounced "hy-poh-kahn-DRY-uh-siss"), a strong, unjustified fear that one has cancer, heart disease, AIDS, or

somatoform disorders Psychological problems in which symptoms of a physical disorder are present without a physical cause.

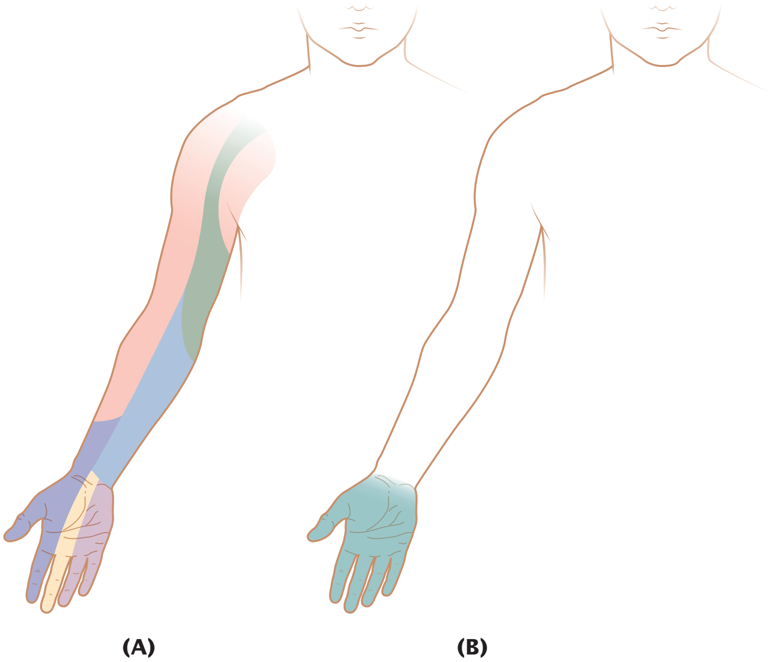
conversion disorder A somatoform disorder in which a person displays blindness, deafness, or other symptoms of sensory or motor failure without a physical cause.

hypochondriasis A somatoform disorder involving strong, unjustified fear of having physical illness.

FIGURE 15.2

Glove Anesthesia

In "glove anesthesia," a form of conversion disorder, lack of feeling stops abruptly at the wrist, as in part B. But as shown in part A, the nerves of the hand and arm blend, so if they were actually impaired, part of the arm would also lose sensitivity. Another neurologically impossible symptom of conversion disorder is sleepwalking at night on legs that are "paralyzed" during the day.



some other serious physical problem. In some ways, hypochondriasis is like an anxiety disorder in that it involves health concerns and includes elements of phobia, panic, and obsessive-compulsive disorder (Olantunji, 2008). People with hypochondriasis make frequent doctor visits to report numerous symptoms and request unnecessary treatment. They may even become "experts" on their most feared diseases, sometimes by endlessly searching health-related Internet Web sites (Hiller et al., 2006; Taylor & Asmundson, 2008).

A related condition, called **somatization disorder**, is characterized by dramatic but vague reports of a multitude of physical problems rather than any specific illness. **Somatoform pain disorder** is marked by complaints of severe, often constant pain (typically in the neck, chest, or back) with no physical cause. In **body dysmorphic disorder**, the person is intensely distressed about an imagined abnormality of the skin, hair, face, or other bodily area. The person may become preoccupied with the imagined deformity or imperfection, avoid social contacts, become dysfunctional, and even seek unnecessary corrective surgery (Veale, 2009).

Some cases of somatoform disorder may be related to childhood experiences in which a person learns that symptoms of physical illness bring special attention, care, and privileges (Abramowitz & Braddock, 2006; Barsky et al., 1994). Others, including conversion disorder, may be triggered by severe stressors (Ballmaier & Schmidt, 2005; Ovsiew, 2006; Spiegel, 1994). Cognitive factors also come into play. When given information about their health, people with hypochondriasis are strongly biased to focus on threat-confirming information but to ignore reassuring information (Eifert, Zvolensky, & Louis, 2008). Abnormal serotonin functioning has also been associated with hypochondriasis, and various combinations of neurochemical and social skill deficits appear to accompany conversion disorder and body dysmorphic disorder (Brodino et al., 2008; Eifert, Zvolensky, & Louis, 2008).

Based on such findings, many researchers have adopted a diathesis-stress approach to explaining somatoform disorders. The results of their work suggest that certain people may have biological and psychological traits that make them especially vulnerable to somatoform disorders, particularly when combined with a history of physical illness. Among these traits are self-consciousness and oversensitivity to

somatization disorder A somatoform disorder in which there are numerous physical complaints without verifiable physical illness.

somatoform pain disorder A somatoform disorder marked by complaints of severe pain with no physical cause.

body dysmorphic disorder A somatoform disorder characterized by intense distress over imagined abnormalities of the skin, hair, face, or other areas of the body.

physical sensations. If such people experience a number of long-lasting stressors, intense emotional conflicts, or severe traumas, they are more likely than others to display physical symptoms in association with emotional arousal (Abramowitz & Braddock, 2006; Siti, 2004).

Sociocultural factors may shape the nature of some somatoform disorders. In many Asian, Latin American, and African cultures, it is not unusual for people to experience severe physical symptoms in association with psychological or interpersonal conflicts (Weiss et al., 2009; recall our earlier examples of *ataques de nervios* and *koro)*. However, the overall *rate* of somatoform disorders appears to be about the same across cultures (Becker, 2004; Kohrt et al., 2005).

Photofest

A Famous Case of Dissociative Identity Disorder

In this scene from the film *Sybil,* Sally Field portrays a woman diagnosed with dissociative identity disorder, also known as multiple personality disorder. Sybil appeared to have as many as seventeen distinct personalities. The causes of such dramatic cases, and the reasons behind their increasing prevalence during the 1970s is a matter of intense debate.

Dissociative Disorders

Have you ever driven for hours on a boring highway and suddenly realized that you couldn't remember anything about the previous half-hour? This is a common experience, but when disruptions in a person's memory, consciousness, or identity are more intense and long-lasting, they are known as **dissociative disorders**. These disruptions can come on gradually, but they usually occur suddenly and last from a few hours to many years.

Consider the case of 18-year-old "Jane Doe," who was found lying in the fetal position outside a New York City youth shelter in October 2009. She claimed to have no memory of her name, where she came from, or how she got where she was (Moore, 2009). After her picture was shown on national television, a viewer identified her as Kacie Peterson. Kacie displayed a dissociative disorder known as **fugue reaction** or **dissociative fugue** (pronounced "fewg"), which is characterized by sudden wandering and loss of memory for (or confusion about) personal identity. In some cases, the person adopts an entirely new identity. A related disorder called **dissociative amnesia** also involves sudden loss of memory about personal information, but the person does not leave home or create a new identity. These rare conditions attract intense publicity because they are so dramatic.

The most famous dissociative disorder is **dissociative identity disorder (DID)**, formerly known as—and still commonly called—*multiple personality disorder* (*MPD*). A person diagnosed with DID appears to have more than one identity, each of which speaks, acts, and writes in a different way. Each personality seems to have its own memories, wishes, and (often conflicting) impulses. Here is a case example (Spitzer et al., 1994):

> Mary, a pleasant and introverted 35-year-old social worker, was referred to a psychiatrist for hypnotic treatment of chronic pain. At an early interview, she mentioned the odd fact that though she had no memory of using her car after coming home from work, she often found that it had been driven fifty to one hundred miles overnight. It turned out that she also had no memory of large parts of her childhood. Mary rapidly learned self-hypnosis for pain control, but during one hypnotic session, she suddenly began speaking in a hostile manner. She told the doctor that her name was Marian and that it was "she" who had been taking long evening drives. She also called Mary "pathetic" for "wasting time" trying to please other people. Eventually, six other identities emerged, some of whom told of having experienced parental abuse in childhood.

During the 1970s, there was a minor "epidemic" of DID, as well as an increase in the number of alternative personalities per case; some patients reported over forty of them (Castelli, 2009). This upsurge in DID may have occurred because clinicians were looking for it more carefully or because the conditions leading to it became more prevalent, but it may have also been influenced by movies such as *Sybil* and by tell-all books written by people who had been diagnosed with DID (Kihlstrom, 2005). These

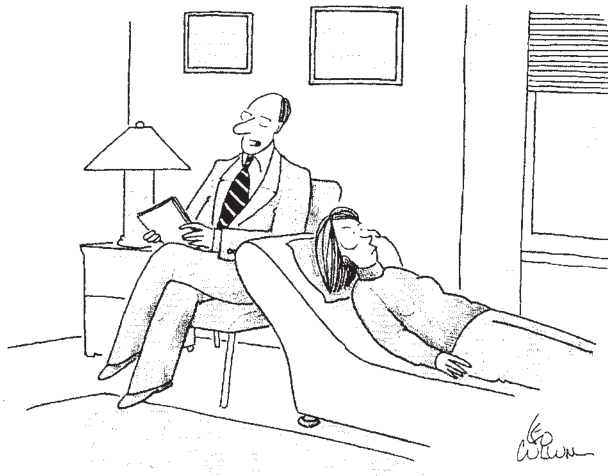
dissociative disorders Rare conditions that involve sudden and usually temporary disruptions in a person's memory, consciousness, or identity.

fugue reaction (dissociative fugue) A dissociative disorder involving sudden loss of memory and possible assumption of a new identity in a new location.

dissociative amnesia A dissociative disorder marked by a sudden loss of memory.

dissociative identity disorder (DID) A dissociative disorder in which a person reports having more than one identity.

The debate and skepticism about dissociative identity disorder—including whether it may be caused by therapists' expectations—is not confined to professional journals. This drawing appeared in *The New Yorker* magazine.



"Would it be possible to speak with the personality that pays the bills?"

© Leo Cullum/The New Yorker Collection/www.cartoonbank.com

media influences may have increased the status of DID as a socioculturally approved method of expressing distress (Hacking, 1995; Spanos, 1994).

How do dissociative disorders develop? Psychodynamic theorists see massive repression of unwanted impulses or memories as the basis for creating a "new person" who acts out otherwise unacceptable impulses or recalls otherwise unbearable memories (Maldonado & Spiegel, 2008; Ross, 1997). Social-cognitive theorists focus on the fact that everyone is capable of behaving in different ways, depending on circumstances (e.g., rowdy in a bar, quiet in a museum), but in rare cases, they say, this variation can become so extreme that an individual feels—and is perceived by others as being—a "different person." Further, dissociative symptoms may be strengthened by reward as people find that a sudden memory loss or shift in behavior allows them to escape stressful situations, responsibilities, or punishment for misbehavior (Lilienfeld & Lynn, 2003; Lilienfeld et al., 2009).

Research on dissociative disorders so far supports four conclusions. First, memory loss and other forms of dissociations are genuine phenomena, and as seen in dissociative fugue, they can sometimes become extreme. Second, many people displaying DID have experienced events they would like to forget or avoid. The majority (some clinicians believe all) have suffered severe, unavoidable, persistent abuse in childhood (Foote et al., 2006; Kihlstrom, 2005). Third, like Mary, most of these people appear to be skilled at self-hypnosis, through which they can induce a trancelike state. Fourth, most found that they could escape the trauma of abuse, at least temporarily, by creating "new personalities" to deal with stress (Spiegel, 1994; van der Hart, Bolt, & van der Kolk, 2005). However, not all abused children display DID, and there is evidence that DID can indeed be triggered by media stories or by therapists who expect to see alternative personalities and use hypnosis and other methods that encourage clients to display them (Lindsay et al., 2004; McHugh, 2009; Rieber, 2006).

This evidence has led some skeptics to question the very existence of multiple personalities (Acocella, 1998; Merckelbach, Devilly, & Rassin, 2002). They point to research showing, for example, that people who display DID may be more aware than they think they are of the memories and actions of each apparent identity (Allen, 2002; Allen & Iacono, 2001). Research on the existence and effects of repressed memories—and the role of therapists in their appearance—is sure to have an impact on our understanding of the causes of DID and the controversy surrounding the disorder (see the memory chapter for more on this controversy).

"In Review: Anxiety, Somatoform, and Dissociative Disorders" presents a summary of our discussion of these disorders.

IN REVIEW Anxiety, Somatoform, and Dissociative Disorders

Disorder	Subtypes	Major Symptoms
Anxiety disorders	Phobias	Intense, unreasonable, disruptive fear of objects or situations
	Generalized anxiety disorder	Excessive anxiety not focused on a specific object or situation; free-floating anxiety
	Panic disorder	Repeated attacks of intense fear involving physical symptoms such as faintness, dizziness, and nausea
	Obsessive-compulsive disorder	Persistent ideas or worries accompanied by ritualistic behaviors performed to neutralize anxiety-driven thoughts
Somatoform disorders	Conversion disorder	A loss of physical ability (e.g., sight, hearing) that is related to psychological factors
	Hypochondriasis	Preoccupation with or belief that one has a serious illness in the absence of any physical evidence
	Somatization disorder	Large number of somatic complaints that occur over several years and are not the result of a known physical disorder
	Somatoform pain disorder	Preoccupation with pain in the absence of physical reasons for the pain
Dissociative disorders	Dissociative amnesia	Sudden loss of memory
	Fugue reaction (dissociative fugue)	Sudden loss of memory, which may result in relocation and the assumption of a new identity
	Dissociative identity disorder (multiple personality disorder)	Appearance within the same person of two or more distinct identities, each with a unique way of thinking and behaving

1. **Concern that it may be triggered by media stories or therapists' suggestions has made ____________ the most controversial of the dissociative disorders.**
2. **A person who sleepwalks but is not able to walk when awake is showing signs of ____________**
3. **Panic disorder sometimes leads to another anxiety disorder called ____________.**

Affective Disorders

Everyone's mood, or *affect,* tends to rise and fall over time. However, when people experience extremes of mood—wild elation or deep depression—for long periods, when they shift rapidly from one extreme to another, and especially when their moods are not consistent with the events around them, they are said to show an **affective disorder** (also known as a **mood disorder**). We will describe two main types: depressive disorders and bipolar disorders.

Depressive Disorders

Depression can range from occasional, normal "down" periods to episodes severe enough to require hospitalization. A person suffering **major depression** (also called **major depressive disorder**) feels sad and overwhelmed, typically losing interest in activities and relationships and taking pleasure in nothing (Getzfeld, 2006; Sloan, Strauss, & Wisner, 2001). Despite the person's best efforts, everything from conversation to bathing is an unbearable, exhausting effort. Changes in eating habits resulting in weight loss or weight gain often accompany major depression, as does sleep disturbance or, less often, excessive sleeping. Problems in working, concentrating, making decisions, and thinking clearly are also common. More often than not, there are also symptoms of an accompanying anxiety disorder (Andreescu et al., 2007; Zimmerman, McDermut, & Mattia, 2000). In extreme cases, depressed people may express false beliefs, or **delusions**—worrying, for example, that the government is planning to punish them. Major depression may come on suddenly or gradually. It may consist of a single episode or, more commonly, repeated depressive periods. These episodes can last weeks or months; the average length of the first one is four to nine months (Durand & Barlow, 2006). Exaggerated feelings of inadequacy, worthlessness, hopelessness, or

affective disorder (mood disorder) A condition in which a person experiences extreme moods, such as depression or mania.

major depression (major depressive disorder) An affective disorder in which a person feels sad and hopeless for weeks or months.

delusions False beliefs, such as those experienced by people suffering from schizophrenia or extreme depression.

guilt are common in major depression (Klein, 2010). Here is a case example (Davison & Neale, 1990, p. 221):

> Mr. J. was a fifty-one-year-old industrial engineer.... Since the death of his wife five years earlier, he had been suffering from continuing episodes of depression marked by extreme social withdrawal and occasional thoughts of suicide.... He drank and, when thoroughly intoxicated, would plead to his deceased wife for forgiveness. He lost all capacity for joy.... Once a gourmet, he now had no interest in food and good wine... and could barely manage to engage in small talk. As might be expected, his work record deteriorated markedly. Appointments were missed and projects haphazardly started and left unfinished.

Depression is not always so extreme (de Graff et al., 2010). In a less severe pattern of depression, called **dysthymic disorder**, the person experiences the sad mood, lack of interest, and loss of pleasure associated with major depression, but less intensely and for a longer period. To qualify as dysthymic disorder, the duration must be at least two years in adults and one year in children. Mental and behavioral disruptions are also less severe; people exhibiting dysthymic disorder rarely require hospitalization.

Major depression occurs at some time in the lives of about 17 percent of people in North America and Europe (Hasin et al., 2005; Kessler & Wang, 2008); in any given year, about 6.7 percent of these populations are experiencing the disorder (Kessler & Wang, 2008). The prevalence and severity of major depression is similar across many ethnic groups (Gonzalez et al., 2010), and it is becoming more common, both in the United States and elsewhere. The World Health Organization estimates that if current trends continue, depression will become the second leading cause of disability and premature death in developed countries (Moussavi et al., 2007; World Health Organization Mental Health Survey Consortium, 2004). However, the incidence of the disorder varies considerably across cultures and subcultures. For example, depression occurs at much higher rates in urban Ireland than in urban Spain, although it is not always clear whether such differences reflect real differences in rates of depression or differences in the application of diagnostic criteria (Judd et al., 2002). There are gender differences in some cultures too. In the United States and other Western countries, females are two to three times more likely than males to experience major depression (Kessler & Wang, 2008), but this difference is smaller in the less economically developed countries of the Middle East, Africa, and Asia (Ayuso-Mateos et al., 2001; Culbertson, 1997; World Health Organization, 2003). Depression can occur at any age, but its prevalence peaks in late adolescence or young adulthood and again during old age (Cross-National Collaborative Group, 2002; Durand & Barlow, 2006; Fassler & Dumas, 1997; Sowdon, 2001).

Depression often occurs in combination with other psychological disorders and medical conditions; it is especially likely to be diagnosed along with posttraumatic stress disorder, obsessive-compulsive disorder, and other anxiety disorders, as well as with substance use disorders, physical disabilities, and recovery from heart attack (Mitra et al., 2005; O'Brien, 2006). As mentioned earlier, some researchers believe that the overlap between anxiety and depression is significant enough to warrant combining them into a single category in the next edition of the *DSM* (Moses & Barlow, 2006).

Suicide and Depression Suicide is associated with a variety of psychological disorders, but it is most closely tied to depression and other affective disorders (Balázs et al., 2006; Holma et al., 2010). Some form of depression has been implicated in 40 to 70 percent of suicides (Angst, Angst, & Stassen, 1999; Oquendo & Mann, 2001). In fact, thinking about suicide is a symptom of depressive disorders. Hopelessness about the future—another depressive symptom—and a desire to seek instant escape from problems are also related to suicide attempts (Brown et al., 2000; Morris, Ciesla, & Garber, 2008; Pompili et al., 2008; Van Orden et al., 2010).

dysthymic disorder An affective disorder involving a pattern of comparatively mild depression that lasts for at least two years.

About thirty-three thousand people in the United States commit suicide each year, or about ninety per day, and ten to twenty times that many people attempt it (Centers for Disease Control and Prevention [CDC], 2009). This puts the U.S. suicide rate at about 11 per 100,000 individuals, making suicide the eleventh leading cause of death. Worldwide, the suicide rate is as high as 25 per 100,000 in some northern and eastern European countries and Japan (Lamar, 2000; World Health Organization, 2003) and as low as 6 per 100,000 in countries with stronger religious prohibitions against suicide, including Greece, Italy, Ireland, and the nations of the Middle East (Lamar, 2000; Ono et al., 2008; World Health Organization, 2003).

Suicide rates also differ considerably, depending on sociocultural factors such as age, gender, and ethnicity (Baca-Garcia et al., 2010; CDC, 2002b, 2002c; NIMH, 2009; Oquendo et al., 2001). In the United States, suicide is most common among people over 65, especially men (Warner, 2010). The suicide rate for men who are 85 or older is 55 per 100,000; for women in this age group, it is only 4 per 100,000 (CDC, 2004). However, since 1950, suicide in the 15-to-24 age group has tripled. And although the rate has begun to level off in the past decade, suicide is still the third leading cause of death, after accidents and homicides, among people in this age group (CDC, 2002b, 2006). Suicide is the second leading cause of death among college students. About ten thousand try to kill themselves each year, and about 10 percent of them succeed. These figures are much higher than for 18- to 24-year-olds in general but much lower than for older adults (NIMH, 2009). Women attempt suicide three times as often as men, but men are four times as likely to actually kill themselves (CDC, 2006). The gender difference is even greater among people who have been diagnosed with depression. In this group, the male suicide rate of 65 per 100,000 is ten times higher than the rate for women (Blair-West et al., 1999; CDC, 1999b).

Suicide rates also differ across ethnic groups (CDC, 2002c; Oquendo et al., 2001). Among males in the United States, for example, the overall rate for American Indians is 15.1 per 100,000, compared with 13.9 for European Americans, 5.7 for Asian Americans, 4.9 for Hispanic Americans, and 5.0 for African Americans. The same pattern of ethnic differences appears among women, though the actual rates are much lower (NIMH, 2009).

Predicting who will commit suicide is difficult. For one thing, suicidal thoughts are quite common—about 3 percent of all adults and as many as 10 percent of college students report having had such thoughts in the previous year (Brener, Hassan, & Barrios, 1999; Kessler, Berglund, Borges, et al., 2005). Still, the results of hundreds of research studies provide some predictive guidelines (Smyth & MacLachian, 2005). The risk of suicide is heightened among people diagnosed with an affective disorder, anxiety disorder, or schizophrenia and people who have suffered extended unemployment (Boardman & Healy, 2001; Joska & Stein, 2008; Khan et al., 2002; Rihmer, 2001). Among older adults, suicide is most common in males who suffer depression over health problems (e.g., Brown, Bongar, & Cleary, 2004). The risk is higher, too, in depressed people who have certain genetic characteristics, have made a specific plan, have given away possessions, and are impulsive (CDC, 2004; Kohli et al., 2010). A previous suicide attempt may not always be a good predictor of eventual suicide because such attempts may have been help-seeking gestures rather than failed efforts to die (Nock & Kessler, 2006). In fact, although about 10 percent of unsuccessful attempters try again and succeed, most people who commit suicide had made no prior attempts (Clark & Fawcett, 1992).

It is often said that people who talk about suicide will never try it. This is a myth. On the contrary, those who say they are thinking of suicide are much more likely than other people to attempt suicide. In fact, most suicides are preceded by some kind of warning, whether direct ("I think I'm going to kill myself") or vague ("Sometimes I wonder if life is worth living"). Failure to recognize or respond to warning signs is a common phenomenon (Valuck et al., 2007). So although not everyone who threatens suicide follows through, if you suspect that someone you know is thinking about suicide, encourage the person to contact a mental health professional or a crisis hotline. If the danger is immediate, make the contact yourself, and ask for advice about what to do. Many suicide attempts—including those triggered by other suicides in the same town or school—can be prevented by social support and other forms of help for people at high risk (CDC, 2004; Mann et al., 2005). For more information, visit suicide-related Web sites such as that of the American Association of Suicidology (www.suicidology.org).

Bipolar Disorders

The alternating appearance of two emotional extremes, or poles, characterizes **bipolar disorders**. We have already described one emotional pole: depression. The other is **mania**, which is an extremely agitated and usually elated emotional state. While in this state, people are utterly optimistic, boundlessly energetic, certain of having extraordinary powers and abilities, and bursting with all sorts of ideas. They become irritated with anyone who tries to reason with them or "slow them down" and may become aggressive or careless enough to pose a danger to themselves or others. During manic episodes, individuals may make impulsive and unwise decisions, such as spending their life savings on foolish schemes (Goldberg & Burdick, 2008; Kessler, Berglund, Demler, et al., 2005; NIMH, 2006).

There are two versions of bipolar disorder, known as bipolar I and bipolar II. In *bipolar I disorder,* manic episodes may alternate with periods of deep depression (Ghaemi, 2008). One bipolar patient described the disorder, which has also been called *manic depression,* this way: "You're really up or you're drop-dead bottom" (Fairbanks, 2009). In many cases, though, these extremes are separated by periods of relatively normal mood (Tohen et al., 2003). Compared to major depression, bipolar I disorder is rare. It occurs in only about 1 percent of adults, and it affects men and women about equally. Another 1 percent of adults display *bipolar II disorder,* in which episodes of major depression alternate with episodes known as *hypomania,* which are less severe than the manic phases seen in bipolar I disorder (Merikangas et al., 2007). Both versions can severely disrupt a person's ability to work or maintain social relationships (Kessler, Berglund, Demler, et al., 2005; NIMH, 2006).

Slightly more common is a pattern of milder mood swings known as **cyclothymic personality** (also called **cyclothymic disorder**), the bipolar equivalent of dysthymic disorder. Cyclothymic disorder involves episodes of depression and mania, but the intensity of both moods is less severe than in bipolar I disorder. As with depression, bipolar disorders are often accompanied by anxiety disorders or substance abuse (Andreescu et al., 2007; Freeman, Freeman, & McElroy, 2002; Ghaemi, 2008). ("In Review: Affective Disorders" summarizes the main types of affective disorders.)

IN REVIEW Affective Disorders

Type	Typical Symptoms	Related Features
Major depression (major depressive disorder)	Deep sadness, feelings of worthlessness, changes in eating and sleeping habits, loss of interest and pleasure	Lasts weeks or months; may occur in repeating episodes; severe cases may include delusions; danger of suicide
Dysthymic disorder	Similar to major depressive disorder, but less severe and longer lasting	Hospitalization is usually not necessary
Bipolar disorder	Alternating extremes of mood, from deep depression to mania, and back	Manic episodes include impulsivity, unrealistic optimism, high energy, severe agitation
Cyclothymic personality (cyclothymic disorder)	Similar to bipolar disorder, but less severe	Hospitalization is usually not necessary

1. The risk of suicide is associated with ____________ more than with any other disorder.

2. Cyclothymic personality is the bipolar version of ____________.

3. Women are ____________ likely than men to try suicide, but men are ____________ likely to succeed.

bipolar disorders Affective disorders in which a person alternates between the emotional extremes of depression and mania.

mania An elated, very active emotional state.

cyclothymic personality (cyclothymic disorder) An affective disorder characterized by an alternating pattern of mood swings that is less extreme than that of bipolar disorders.

Causes of Affective Disorders

LINKAGES Are some psychological disorders inherited? (a link to Biological Aspects of Psychology, p. 84)

Research on the causes of affective disorders has focused on biological, psychological, and sociocultural risk factors. The more of these risk factors people have, the more likely they are to experience an affective disorder.

Biological Factors The role of genetics in affective disorders, especially in bipolar disorders, is suggested by twin studies and family studies (Fullerton et al., 2010; Hayden & Nurnberger, 2006; Kendler et al., 2006). For example, bipolar disorder is much more likely to appear in both members of genetically identical twin pairs than in nonidentical twins (Smoller, 2008). Family studies also show that close relatives of people with a bipolar disorder are more likely than others to develop that disorder themselves (Althoff et al., 2005; Serretti et al., 2009). Major depression is also more likely to be shared among family members, especially by identical twins (Kendler et al., 2009; Levinson, 2006). This genetic influence is especially strong in female twins (Bierut et al., 1999). Findings such as these suggest that genetic influences tend to be stronger for affective disorders, especially for bipolar disorders and severe, early-onset depression, than for most other disorders.

Researchers have already identified certain genetic variations that affect vulnerability to affective disorders (e.g., Joska & Stein, 2008; McMahon et al., 2010; Smoller, 2008; Young et al., 2008). These include genes on chromosome 13 that are involved in the operation of the neurotransmitter serotonin (Hariri et al., 2005; Jacobs et al., 2006; Wilhelm et al., 2006). Still, it is important to recognize that genetic variations alone probably do not cause affective disorders. Rather, genes appear to act in combination with other biological, psychological, and environmental factors. Researchers in the field of epigenetics are investigating how the genes associated with affective disorders can be "turned on" or "turned off" by these factors (Butcher, Mineka, & Hooley, 2010; Levinson et al., 2007).

Other biological factors that may contribute to affective disorders include malfunctions in regions of the brain devoted to mood, imbalances in the brain's neurotransmitter systems, malfunctioning of the endocrine system, disruption of biological rhythms, and underdevelopment in the frontal lobes, hippocampus, or other brain areas (Butcher, Mineka, & Hooley, 2010; Jans et al., 2007; Langan & McDonald, 2009; Shankman et al., 2007; Staley et al., 2006; Strakowski, DelBello, & Adler, 2005). All of these conditions may themselves be influenced by genetics. The brain regions involved in mood are many, including the prefrontal cortex, the hippocampus, the amygdala, and other components of the limbic system (Blumberg et al., 2003; MacQueen et al., 2003). There are so many of these regions, in fact, and so many different pathways through which their activity can be disrupted, that different affective disorders may reflect problems in different brain regions (Davidson et al., 2002; Elliott et al., 2002). Malfunctions in some of the same regions are also involved in the symptoms of anxiety disorders, which may help account for the fact that affective and anxiety disorders often appear together (Middeldorp et al., 2005).

As for the role of neurotransmitters, norepinephrine, serotonin, and dopamine were implicated in affective disorders decades ago when scientists discovered that drugs capable of altering these brain chemicals also relieved affective disorders. Early research suggested that depression was triggered by too little of these neurotransmitters, whereas unusually high levels caused mania. However, the neurochemical causes now appear far more complex. For example, affective disorders may result in part from changes in the sensitivity of the neuronal receptors at which these chemicals have their effects in the brain. The precise nature of these neurotransmitter-receptor mechanisms and just how they affect mood are not yet fully understood.

Affective disorders have also been related to malfunctions in the endocrine system, especially the hypothalamic-pituitary-adrenocortical (HPA) system. As described in the chapter on health, stress, and coping, this system is involved in the body's responses to stress. Research shows, for example, that as many as 70 percent of depressed people secrete abnormally high levels of the stress hormone cortisol (Dinan, 2001; Posener et al., 2000). Studies of identical twins also suggest that higher levels of cortisol are associated with depression (Dinan, 2001; Wichers et al., 2008).

The cycles of mood swings seen in bipolar disorders and in recurring episodes of major depression suggest that affective disorders may be related to stressful triggering events (Hammen, 2005; Keller & Nesse, 2006). They may also be related to disturbances in the body's biological clock, which is described in the chapter on consciousness (Monteleone & Maj, 2008). This second possibility seems especially likely in the 15 percent of depressed people who consistently experience a calendar-linked pattern of depressive episodes known as *seasonal affective disorder* (*SAD*). During months of shorter daylight, these people slip into severe depression, accompanied by irritability and excessive sleeping (Durand & Barlow, 2006). Their depression tends to lift as daylight hours lengthen. Resetting the biological clock through methods such as sleep deprivation or light stimulation has relieved depression in many cases (Lavoie et al., 2009; Lewy et al., 2006; Wu et al., 2009).

Psychological and Social Factors Researchers have come to recognize that whatever biological causes are involved in affective disorders, their effects are always combined with those of psychological and social causes. As mentioned earlier, the very nature of depressive symptoms can depend on the culture in which a person lives. Biopsychosocial explanations of affective disorders also emphasize the impact of anxiety, negative thinking, personality traits, family interactions, and the other psychological and emotional responses triggered by trauma, losses, and other stressful events (Monroe & Reid, 2009; Rice et al., 2006; Steunenberg et al., 2006). For example, the higher incidence of depression among females—and especially among poor, ethnic minority, single mothers—has been attributed to several factors. Women have greater exposure than men to certain adverse experiences during childhood (e.g., sexual abuse) and adulthood (e.g., domestic violence, poverty). When these risk factors combine with depressive ways of thinking and loss of social support, depression becomes more likely (Miranda & Green, 1999; Nolen-Hoeksema, 2006; Whiffen, 2006). Environmental stressors affect men, too, which may be one reason why gender differences in depression are smaller in countries in which men and women face equally stressful lives (Bierut et al., 1999; Maier et al., 1999).

A number of social-cognitive theories suggest that the way people think about their stressors can increase or decrease the likelihood of affective disorders. One of these theories stemmed from the research on *learned helplessness* described in the

© Dan McCoy/Rainbow

Treating SAD

Seasonal affective disorder (SAD) can often be relieved by exposure to full-spectrum light for as little as a couple of hours a day (Terman & Terman, 2005).

chapter on learning. Just as animals become inactive and appear depressed when they have no control over negative events (El Yacoubi et al., 2003), humans may experience depression as a result of feeling incapable of controlling certain aspects of their lives, especially the stressors confronting them (Alloy et al., 2008; Klein & Seligman, 1976; Seligman, 1991). But most of us have limited control over our lives, so why aren't we all depressed? The ways in which people learn to think about events in their lives may hold the key. For example, Aaron Beck's cognitive theory of depression suggests that depressed people develop mental habits of (1) blaming themselves when things go wrong, (2) focusing on and exaggerating the negative side of events, and (3) jumping to overly generalized, pessimistic conclusions (Beck, 1967, 1976, 2008). Such cognitive habits, says Beck, are errors that lead to depressing thoughts and other symptoms of depression (Beck & Beck, 1995; Evans et al., 2005; Joormann, Teachman, & Gotlib, 2009). Depressed people, in fact, do tend to think about significant negative events in ways that are likely to increase or prolong their depression (Gotlib et al., 2004; Morris, Ciesla & Garber, 2008; Strunk, Lopez, & DeRubeis, 2006).

Social-cognitive theories of depression are somewhat consistent with the psychodynamically oriented *object relations* approach discussed in the chapter on personality. Both views suggest that negative patterns of thinking can be acquired through maladaptive experiences in childhood. For example, research indicates that children whose early relationships with parents or other primary caregivers were characterized by deprivation or abuse are especially likely to develop depression in later life (Gotlib & Hammen, 1992). It may be that close, protective, predictable, and responsive early relationships are necessary if children are to form healthy views of themselves, positive expectations about others, and a sense of control over the environment (Bowlby, 1980; Ivanova & Israel, 2005; Main, 1996).

Severe, long-lasting depression is especially common among people who see their lack of control or other problems as caused by a permanent, generalized lack of personal competence rather than by a temporary condition or an external cause (Seligman et al., 1988). This *negative attributional style* is regarded by some researchers as a partly inherited trait that leaves people prone to depression because they attribute negative events to their own characteristics and believe that they will never be capable of doing better (Alloy et al., 2006; Ball, McGuffin, & Farmer, 2008; Hankin, Fraley, & Abela, 2005; Hunt & Forand, 2005). Are depressed people's unusually negative beliefs about themselves responsible for their depression, or are they merely symptoms of it? A number of studies have assessed the attributional styles of large samples of nondepressed people and then kept in touch with them to see if, in the face of equivalent stressors, individuals with negative self-beliefs are more likely to become depressed. These longitudinal studies suggest that a negative attributional style is in fact a risk factor for depression, not just a result of being depressed (Alloy et al., 2006; Evans et al., 2005; Keenan et al., 2008). In one study, for example, adolescents who held strong negative self-beliefs were more likely than other youngsters to develop depression when faced with stress later in life (Lewinsohn, Joiner, & Rohde, 2001).

Social-cognitive theorists also suggest that whether depression continues or worsens depends in part on how people respond once they start to feel depressed. Those who continuously dwell on negative events, on why they occur, and even on their feelings of depression are likely to feel more and more depressed (Just & Alloy, 1997; McMurrich & Johnson, 2008; Rimes & Watkins, 2005). According to Susan Nolen-Hoeksema (1990, 2001), this *ruminative style* is especially common in women and may help explain gender differences in the frequency of depression. When men start to feel sad, she says, they tend to use a *distracting style.* That is, they engage in activity that distracts them from their concerns and helps bring them out of their depressed mood (Hankin & Abramson, 2001; Just & Alloy, 1997; Nolen-Hoeksema, Morrow, & Fredrickson, 1993).

Notice that social-cognitive explanations of depression are consistent with the diathesis-stress approach to disorder. They suggest that certain cognitive styles constitute a predisposition (or diathesis) that makes a person vulnerable to depression. The actual occurrence of depression is then made more likely by stressors. In fact, most episodes of major depressive disorder are preceded by the onset of major stressors, such as the loss of a loved one. As suggested in the chapter on health, stress, and coping, the depressing effects of these stressors are likely to be magnified by lack social support, inadequate coping skills, and the presence of other stressful conditions such as poverty (e.g., Belik et al., 2007; Stice, Ragan, & Randall, 2004).

Given the number and complexity of biological, psychological, social, and situational factors potentially involved in causing affective disorders, the biopsychosocial approach and the diathesis-stress model appear to be especially appropriate guides to future research (Kendler, Gardner, & Prescott, 2006). Studies based on these guides are already bearing fruit. One study looked at the role of genetics and stressful events in shaping mood disorders in a large group of female twin pairs. Both factors were associated with major depression. Specifically, the women at highest genetic risk were also the most likely to become depressed following a significant stressor (Kendler, Thornton, & Gardner, 2000, 2001; Kendler et al., 2005). Another study found that people with a particular version of a single gene were more likely than others to experience depressive symptoms in relation to stressful events (Caspi, Sugden, et al., 2003). On the basis of studies like these, Kenneth Kendler and his colleagues (Kendler, Gardner, & Prescott, 2002) have described specific sets of risk factors for depression in women that appear at five developmental stages: childhood, early adolescence, late adolescence, adulthood, and the year preceding the diagnosis of depression.

In the final analysis, it may turn out that each subtype in the spectrum of affective disorders is caused by a unique combination of factors. The challenge for researchers is to identify these subtypes and map out their causal ingredients (Eshel & Roiser, 2010).

Schizophrenia

Schizophrenia (pronounced “skit-soh-FREE-nee-uh”) is a pattern of extremely disturbed thinking, emotion, perception, and behavior that seriously impairs the ability to communicate and relate to others and disrupts most other aspects of daily functioning (Freedman, 2003). It is one of the most severe and disabling of all mental disorders. The core symptoms of schizophrenia are seen virtually everywhere in the world, occurring in 1 to 2 percent of the population (American Psychiatric Association, 2000; NIMH, 2006). In the United States, it appears about equally in various ethnic groups, but like most disorders, it tends to be diagnosed more frequently in economically disadvantaged populations. Schizophrenia occurs about equally in men and women, although in women it generally appears later in life, tends to be less severe, and responds better to treatment (Aleman, Kahn, & Selten, 2003; American Psychiatric Association, 2000; Häfner, 2003).

Schizophrenia tends to develop in adolescence or early adulthood. About 75 percent of the time, its onset is gradual, with the earliest signs appearing as much as five years before the first major schizophrenic episode. In other cases, the onset is more rapid. About 40 percent of people with schizophrenia improve with treatment and are able to function reasonably well. The rest show continuous or intermittent symptoms that permanently disrupt their functioning (Harrow & Jobe, 2005) and, especially for those with a drug abuse problem, may lead to homelessness (Timms, 2005).

One of the best predictors of the course of schizophrenia is *premorbid adjustment,* which is the level of functioning a person had achieved before schizophrenic symptoms first appeared. Improvement is more likely in those who had reached higher levels of education and occupation and who had established supportive relationships with family and friends (Keshavan et al., 2005; Rabinowitz et al., 2002).

Symptoms of Schizophrenia

People with schizophrenia have problems with both how they think and what they think. The nineteenth-century psychiatrist Eugen Bleuler (pronounced “OY-gun BLOY-lur”) coined the word *schizophrenia,* or “split mind,” to refer to the oddities of

schizophrenia A severe and disabling pattern of disturbed thinking, emotion, perception, and behavior.

schizophrenic thinking. However, schizophrenia does not mean "split personality," as in dissociative identity disorder (multiple personality disorder). It refers instead to a splitting of normally integrated mental processes, such as thoughts and feelings. For instance, some schizophrenics may giggle while claiming to feel sad.

LINKAGES How do individuals with schizophrenia think? (a link to Cognition and Language, p. 285)

Schizophrenic thought and language are often disorganized, as illustrated in the following letter that arrived in the mail several years ago:

> Dear Sirs:
> Pertaining to our continuing failure to prosecute violations of minor's rights to sovereign equality which are occurring in gestations being compromised by the ingestation of controlled substances, . . . the skewing of androgyny which continues in female juveniles even after separation from their mother's has occurred, and as a means of promulflagitating my paying Governor Hickel of Alaska for my employees to have personal services endorsements and controlled substance endorsements, . . . the Iraqi oil being released by the United Nations being identified as Kurdistanian oil, and the July, 1991 issue of the Siberian Review spells President Eltsin's name without a letter *y*.

People with schizophrenia often use new words, known as *neologisms,* that are usually nonsensical and have meaning only to them. The appearance of "promulflagitating" in the preceding letter is one example. The letter also illustrates *loose associations,* the tendency for one thought to be logically unconnected or only slightly related to the next. Sometimes the associations are based on double meanings or on the way words sound (*clang associations*). For example, "My true family name is Abel or A Bell. We descended from the clan of Abel, who originated the bell of rights, which we now call the bill of rights." In the most severe cases, a jumble of words known as *word salad* reflects utterly chaotic thoughts: "Upon the advisability of held keeping, environment of the seabeach gathering, to the forest stream, reinstatement to be placed, poling the paddleboat, of the swamp morass, to the forest compensation of the dunce" (Lehman, 1967, p. 627).

The *content* of schizophrenic thinking is also disturbed. Often it includes delusions, or false beliefs, as in this case (Stefanidis, 2006):

> Erin Stefandis was a graduate student in the neuroscience program at the University of British Columbia. He prided himself on his ability to think rationally, yet he was convinced that rats were living in his head and eating his brain. He knew that this should cause dramatic cognitive and behavioral impairments and ultimately death, but he believed his brain was unique and was able to regenerate brain cells quickly enough to keep him alive and well. When this illogical belief was challenged by his doctor, he said he believed in "deep meaning," which is "truth that exists at a higher level than logic."

Delusions tend to fall into three general categories (Kimhy et al., 2005). *Delusions of influence* focus on the belief that one's body, thinking, or behavior are being affected or controlled by external forces. Patients with these delusions might claim that the CIA has implanted a control device in their brains. They might believe that other people's thoughts are appearing in their mind (thought insertion) or that they can broadcast their thoughts to others (thought broadcasting). *Self-significant delusions* involve exaggerated beliefs about oneself. People with these delusions may believe, for example, that certain TV commercials contain coded messages about their innermost secrets; that they are truly an emperor, the pope, or even God (delusions of grandeur); or that they are guilty of some terrible sin. People displaying *delusions of persecution* believe that others are out to harass or harm them. They may claim, for example, that they are always being followed, that space aliens are trying to steal their internal organs, or that they are the targets of an assassin. These delusions tend to be deeply entrenched and resistant to change, no matter how strong the evidence against them (Minzenberg et al., 2008;Woodward et al., 2006).

hallucinations A symptom of disorder in which people perceive voices or other stimuli when there are no stimuli present.

Hallucinations, or false perceptions, are common, often taking the form of voices. The voices may sound like an overheard conversation, or they may tell the person to

FIGURE 15.3

Brain Activity During Hallucinations

These are brain images of a 23-year-old schizophrenia patient who was experiencing hallucinations of rolling heads that spoke to him. PET scans revealed heightened activity in visual and auditory (language) *association* cortex rather than in the *primary* cortex regions for these senses. The posterior cingulate cortex (part of the limbic system) was also activated; it is known to be affected by drugs that produce hallucinations (Silbersweig et al., 1995).

Catatonic Stupor

The symptoms of schizophrenia often occur in characteristic patterns. This woman's lack of motivation and other negative symptoms of schizophrenia are severe enough that she appears to be in a catatonic stupor. Such patients may become rigid or, as in this case, show a *waxy flexibility* that allows them to be "posed" in virtually any position. Diagnosticians using the traditional subtype system would probably label her as displaying catatonic schizophrenia.

© Grunnitus/Photo Researchers, Inc.

do or not to do certain things. They may also comment on, narrate, or (most often) harshly criticize the person's actions or characteristics. Hallucinations can also create sights, smells, tastes, and touch sensations even when no external stimuli are present. As shown in Figure 15.3, the brain areas activated during hallucinations are related to those that respond to real sights and sounds (Alerman & Larøi, 2008; Shergill et al., 2000; Simons et al., 2010).

People with schizophrenia often report that they cannot focus their attention. They may feel overwhelmed as they try to attend to everything at once. Perceptual disorders may also appear. The person may feel detached from the world and see other people as flat cutouts. The body may feel like a machine, or parts of it may seem to be dead or rotting. The emotional expressiveness of people with schizophrenia is often muted, but when they do show emotion, it is frequently exaggerated or inappropriate. They may cry for no apparent reason or fly into a rage in response to a simple question.

Some schizophrenia patients are extremely agitated, constantly moving their limbs, making facial grimaces, or pacing the floor in highly ritualistic sequences. Others become so withdrawn that they move very little. Lack of motivation and poor social skills, deteriorating personal hygiene, and an inability to function in everyday situations are other common characteristics of schizophrenia.

Categorizing Schizophrenia

DSM-IV-TR lists five major subtypes of schizophrenia: paranoid, disorganized, catatonic, undifferentiated, and residual (see Table 15.4). These subtype labels convey a certain amount of useful information, but they don't always provide an accurate picture of patients' behavior because some symptoms appear in more than one subtype. Further, people originally diagnosed in one subtype can later display characteristics

TABLE 15.4 Subtypes of Schizophrenia

Mental health professionals still use these *DSM-IV-TR* subtypes when diagnosing schizophrenia, but many researchers now tend to categorize patients in terms of whether positive or negative symptoms of schizophrenia predominate in a given case (Villalta-Gil et al., 2006).

Type	Prevalence	Prominent Features
Paranoid schizophrenia	40% of schizophrenics; usually appears after age 25–30	Delusions of grandeur or persecution; anger; anxiety; argumentativeness; extreme jealousy; onset often sudden; signs of impairment may be subtle
Disorganized schizophrenia	5% of all schizophrenics; high prevalence in homeless population	Delusions; hallucinations; incoherent speech; facial grimaces; inappropriate laughter or giggling; neglected personal hygiene; loss of bladder or bowel control
Catatonic schizophrenia	8% of all schizophrenics	Disordered movement, alternating between immobility (stupor) and wild excitement. In stupor, the person does not speak or attend to communication
Undifferentiated schizophrenia	40% of all schizophrenics	Patterns of disordered behavior, thought, and emotion that do not fall easily into any other subtype
Residual schizophrenia	Varies	Applies to people who have had prior episodes of schizophrenia but are not currently displaying symptoms

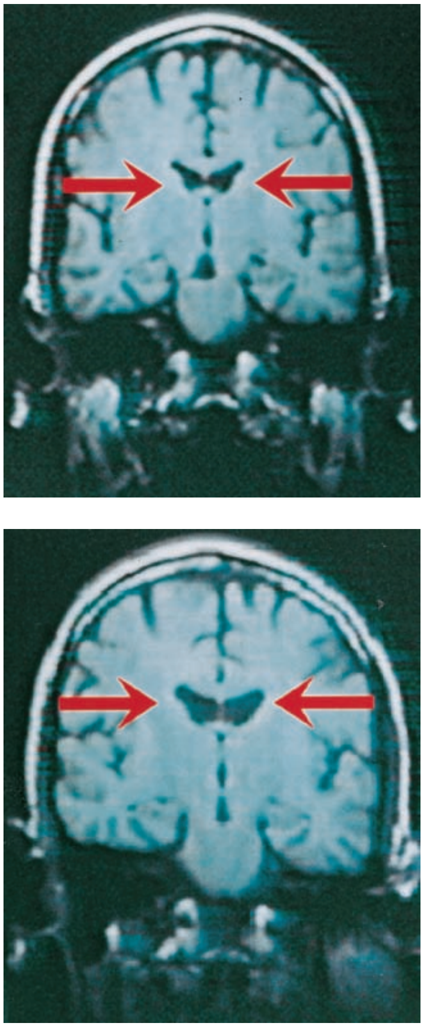
of another subtype. Finally, the *DSM-IV-TR* subtypes may not be linked very closely to the various biological conditions thought to underlie schizophrenia (Barch, 2006; Fenton & McGlashan, 1991; Jablensky, 2006).

Accordingly, many researchers now categorize schizophrenia in ways that focus more precisely on the kinds of symptoms that patients display. One method of categorizing schizophrenia highlights the positive or negative aspects of symptoms. Disorganized thoughts, delusions, and hallucinations are sometimes called **positive symptoms** of schizophrenia because they appear as undesirable *additions* to a person's mental life (Iancu et al., 2005; Smith et al., 2006). In contrast, the absence of pleasure and motivation, lack of emotional reactivity, social withdrawal, reduced speech, and other deficits seen in schizophrenia are sometimes called **negative symptoms** because they appear to *subtract* elements from normal mental life (Batki et al., 2008). Describing patients in terms of positive and negative symptoms does not require that they be placed in one category or the other. In fact, many patients exhibit both positive and negative symptoms. However, it is important to know whether negative or positive symptoms predominate, because when symptoms are mainly negative, as they are in about 25 percent of schizophrenia patients, the disorder is usually more severe and less responsive to treatment (Kirkpatrick et al., 2006; Milev et al., 2005; Prikryl et al., 2006). In these cases, patients typically experience long-term disability.

Another way of categorizing schizophrenia symptoms focuses on whether they are *psychotic* (hallucinations, delusions), *disorganized* (incoherent speech, chaotic behavior, inappropriate affect), or *negative* (e.g., lack of speech or motivation). Other researchers have suggested categorizing schizophrenia symptoms as positive, negative, or depressive (Häfner & Maurer, 2000). The fact that, like positive and negative symptoms, these dimensions of schizophrenia are to some extent independent from one another suggests to some researchers that each symptom cluster or dimension may ultimately be traceable to different causes. For this reason, schizophrenia is often referred to as the *schizophrenia spectrum,* implying that each cluster may develop differently and require different treatments (Tsuang, Stone, & Faraone, 2000). The schizophrenia spectrum also includes other diagnoses that share features with schizophrenia. For example, people diagnosed with *schizoaffective disorder* show symptoms of both schizophrenia and depression. *Schizophreniform disorder* is characterized by schizophrenia-like symptoms that do not last as long as those typically seen in schizophrenia.

positive symptoms Schizophrenic symptoms such as disorganized thoughts, hallucinations, and delusions.

negative symptoms Schizophrenic symptoms such as absence of pleasure, lack of speech, and flat affect.



National Institute of Mental Health

FIGURE 15.4

Brain Abnormalities in Schizophrenia

Here is a magnetic resonance imaging (MRI) comparison of the brains of identical twins. The schizophrenic twin (bottom photo) has greatly enlarged ventricles (see arrows) and correspondingly less brain tissue, including in the hippocampal area, a region involved in memory and emotion. The same results appeared in fourteen other identical-twin pairs. By contrast, no significant differences appeared between members of a seven-pair control group of normal identical twins (Suddath et al., 1990). These results support the idea that brain abnormalities are associated with schizophrenia and, because identical twins have the same genes, that such abnormalities may stem from nongenetic factors (Baare et al., 2001).

Causes of Schizophrenia

The search for the causes of schizophrenia has been more intense than for any other psychological disorder. The findings so far confirm one thing: As with other disorders, there are biological, psychological, and social factors at work in causing or worsening all forms of schizophrenia (Sullivan, Kendler, & Neale, 2003; Tandon, Nasrallah, & Keshaven, 2009).

Biological Factors Research in behavioral genetics shows that schizophrenia runs in families (Dubertret et al., 2004; Gottesman et al., 2010; Kasper & Papadimitriou, 2009). One family study found, for instance, that 16 percent of the children of schizophrenic mothers developed schizophrenia themselves over a twenty-five-year period, versus only 2 percent of the children of nonschizophrenic mothers (Parnas et al., 1993). Even if they are adopted by families in which there is no schizophrenia, the children of schizophrenic parents are ten times more likely to develop schizophrenia than adopted children whose biological parents are not schizophrenic (Kety et al., 1994; Tienari et al., 2003). Still, it is unlikely that a single gene transmits schizophrenia (Chumakov et al., 2002; Plomin & McGuffin, 2003). For example, among identical-twin pairs in which one member displays schizophrenia, 40 percent of the other members will too, but 60 percent will not (McGue, 1992). It is more likely that some people inherit a predisposition, or diathesis, for schizophrenia that involves several genes and that these genetic factors combine with other genetic and nongenetic factors to cause the disorder (DeRosse et al., 2006; Fan et al., 2006; Law, Cotton, & Berger, 2006; Levitt et al., 2006; Vazza et al., 2007).

The search for biological causes of schizophrenia also focuses on a number of abnormalities in the structure, functioning, and chemistry of the brain that tend to appear in people with schizophrenia (e.g., Andrews et al., 2006; Lynall et al., 2010; Neves-Pereira et al., 2005; Rasmussen et al., 2010; Tamminga & Holcomb, 2005). Numerous brain-imaging studies have shown that compared with other mental patients, many schizophrenia patients have less tissue in thalamic regions, prefrontal cortex, and some subcortical areas (Behrendt, 2006; Conklin & Iacono, 2002; Csernansky et al., 2004; Ettinger et al., 2007; Goto, Yang, & Otani, 2010; Javitt, Kantrowitz, & Lajtha, 2009). As shown in Figure 15.4, shrinkage of tissue in these regions leads to corresponding enlargement of the brain's fluid-filled spaces, called *ventricles.* The brain areas in which anatomical abnormalities have been found are active in emotional expression, thinking, and information processing—functions that are disordered in schizophrenia (Conklin & Iacono, 2002; Csernansky et al., 2004; Highley et al., 2003; Pol et al., 2002; Selemon et al., 2003; Velakoulis et al., 2006). Enlarged ventricles and reduced prefrontal cortex are more often found in patients whose schizophrenic symptoms are predominantly negative (Sigmundsson et al., 2001). Continued tissue loss has been associated with worsening of negative symptoms (Ho et al., 2003).

Hundreds of studies of brain functioning in people diagnosed with schizophrenia provide general support for the idea that their impairments in information processing and other cognitive abilities are related to structural abnormalities (Gur et al., 2000; Jeon & Polich, 2003; Lee, Williams, et al., 2003; Zanelli et al., 2010). For example, patients with predominantly negative symptoms are especially likely to display cognitive deficits associated with prefrontal cortex problems (Wible et al., 2001). This research is providing important clues (Barch, 2006), but it will take even more research to determine the extent to which, or exactly how, specific structural abnormalities are related to the cognitive problems seen in various forms of schizophrenia.

Researchers are also investigating the possibility that abnormalities in brain chemistry—especially in neurotransmitter systems that use dopamine—play a role in causing or intensifying schizophrenic symptoms (Javitt, Kantrowitz, & Lajtha, 2009; Tan et al., 2007). Because drugs that block the brain's dopamine receptors often reduce hallucinations, delusions, disordered thinking, and other positive symptoms of schizophrenia, some investigators speculate that schizophrenia results from excess dopamine.

However, the relationship between dopamine and schizophrenia is quite complex (Carlsson & Lecrubier, 2004). For example, it may be that changes in the ratio of dopamine to other neurochemicals, particularly in the region of the thalamus, are involved in the difficulties experienced by people with schizophrenia in distinguishing genuine sights and sounds from those produced by neural "noise" within the brain (Buchsbaum et al., 2006; Winterer, 2006).

Some researchers are seeking to integrate genetic, neurological, and environmental explanations of schizophrenia by looking for *neurodevelopmental abnormalities* (Meyer et al., 2005; Rapoport, Addington, & Frangou, 2005). Perhaps, they say, some forms of schizophrenia arise from disruptions in brain development during the period from before birth through childhood, when the brain is growing and its various functions are maturing. Studies have shown, for instance, that prenatal exposure to physical traumas, influenza, or other viral infections is associated with increased risk for developing schizophrenia (AbdelMalik et al., 2003; Brown & Derkits, 2010; Subotnik et al., 2006). Similarly, low-birth-weight children are more likely to have the brain abnormalities described earlier. These abnormalities are especially likely in children of schizophrenic parents (Cannon et al., 1993; Lawrie et al., 2001). Even parental age may make a difference. Children whose fathers were older than 45 at the time the children were conceived appear to be at elevated risk for developing schizophrenia, possibly because of a sperm cell mutation (Dalman & Allebeck, 2002).

The expression of a genetically transmitted predisposition for brain abnormality may be enhanced by environmental factors such as maternal drug use during pregnancy, oxygen deprivation or other complications during birth, or childhood malnutrition (Sørensen et al., 2003; NIMH, 2008b). For example, as mentioned earlier, smaller-than-normal prefrontal lobes and other brain structures appear to constitute an inherited predisposition for schizophrenia. However, reduced brain growth alone is not sufficient to cause the disorder. When only one member of an identical-twin pair has schizophrenia, both tend to have unusually small brains, but the schizophrenic twin's brain in each pair is the smaller of the two (Baare et al., 2001). This finding suggests that some environmental influence caused degeneration in an already underdeveloped brain, making it even more prone to function abnormally.

Psychological and Sociocultural Factors Psychological processes and sociocultural influences can contribute to the appearance of schizophrenia and influence its course (Kealy, 2005; Vahia & Cohen, 2009). These include factors such as dysfunctional cognitive habits, the stress of urban living, being an immigrant, and exposure to stressful family communication patterns (Mueser & Jeste, 2009; van Os, Rutten, & Poulton, 2008). For example, criticism by family members—sometimes called *expressed emotion*—is associated with more severe symptoms (Nomura et al., 2005). And schizophrenia patients living with relatives who are critical, unsupportive, or emotionally overinvolved are especially likely to relapse following improvement (Hooley, 2004). Family members' negative attitudes may be a source of stress that increases the chances that disruptive or odd behaviors will persist or worsen (Rosenfarb et al., 1995). Keep in mind, though, that the strange and often disturbing behavior of a family member with schizophrenia can place tremendous strain on the rest of the family, making it harder for them to remain helpful and supportive (Kymalainen et al., 2006; Rosenfarb, Bellack, & Aziz, 2006). In any case, patients who receive help in coping with potentially damaging family influences tend to have better long-term outcomes (Bustillo et al., 2001; Velligan et al., 2000).

Vulnerability Theory All the causal theories of schizophrenia discussed so far are consistent with the diathesis-stress approach, which assumes that various forms of stress can activate a person's predisposition for disorder (Stahl, 2007). ("In Review: Schizophrenia" summarizes these theories, as well as the symptoms of schizophrenia.) The diathesis-stress approach is embodied in the *vulnerability theory* of schizophrenia

IN REVIEW Schizophrenia

Aspect	Key Features
Common Symptoms	
Disorders of thought	Disturbed content, including delusions; disorganization, including loose associations, neologisms, and word salad
Disorders of perception	Hallucinations; poorly focused attention
Disorders of emotion	Flat affect; inappropriate tears, laughter, or anger
Possible Causes	
Biological	Genetics; abnormalities in brain structure; abnormalities in dopamine systems; neurodevelopmental problems
Psychological	Learned maladaptive behavior; disturbed patterns of family communication

1. The ____________ approach forms the basis of the vulnerability theory of schizophrenia.

2. Hallucinations are ____________ symptoms of schizophrenia; lack of emotion is a ____________ symptom.

3. Patients with schizophrenia who were able to finish school are ____________ likely to show improvement.

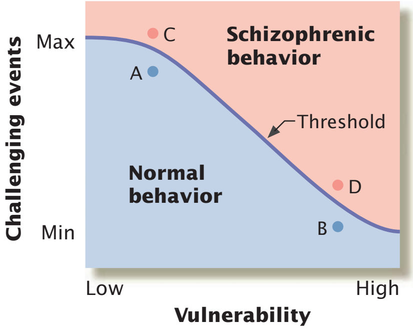


FIGURE 15.5

The Vulnerability Theory of Schizophrenia

According to this theory, a person can cross the threshold into schizophrenia as a result of many combinations of predisposition and stress. A strong predisposition for schizophrenia and little environmental stress (point D), a weak predisposition and a lot of stress (point C), or any other sufficiently potent combination can lead to the disorder. Points A and B represent combinations of vulnerability and stress that would not lead to schizophrenia.

Source: J. Zubin and B. Spring. "A New View of Schizophrenia". *Journal of Abnormal Psychology*, 86, p. 110. Copyright © 1977 by the American Psychological Association. Adapted with permission.

(Cornblatt & Erlenmeyer-Kimling, 1985; Zubin & Spring, 1977). This theory suggests that (1) vulnerability to schizophrenia is mainly biological, (2) different people have differing degrees of vulnerability, (3) vulnerability is influenced partly by genetic influences on development and partly by neurodevelopmental abnormalities associated with environmental risk, and (4) psychological components—such as exposure to poor parenting or high-stress families or having inadequate coping skills—may help determine whether schizophrenia actually appears and may also influence the course of the disorder (Walker & Diforio, 1998; Wearden et al., 2000).

Many different blends of vulnerability and stress can lead to schizophrenia, as Figure 15.5 illustrates. People whose genetic characteristics or developmental influences leave them vulnerable to developing schizophrenia may be especially likely to do so if they are later exposed to learning experiences, family conflicts, and other stressors that trigger and maintain schizophrenic patterns of thought and action. Those same experiences and stressors would not be expected to lead to schizophrenia in people who are less vulnerable to developing the disorder. In other words, schizophrenia is a highly complex disorder—probably a spectrum of related disorders (Kirkpatrick et al., 2001; Lenzenweger, McLachlan, & Rubin, 2007)—whose origins lie in many biological, psychological, and social domains, some of which are yet to be discovered (Gilmore, 2010).

Personality Disorders

Personality disorders are long-standing, inflexible ways of behaving that are not so much severe mental disorders as dysfunctional styles of living (Clarkin, 2006). These disorders affect all areas of functioning and, beginning in childhood or adolescence, create problems for those who display them and for others (Cohen, 2008; Millon & Davis, 1996). Some psychologists view personality disorders as interpersonal strategies (Kiesler, 1996) or as the extreme, rigid, and maladaptive expressions of personality traits (Widiger, 2008). The ten personality disorders listed on Axis II of *DSM-IV-TR* are grouped into three clusters that share certain features (see Table 15.5).

The *odd-eccentric* cluster—referred to as *cluster A*—includes paranoid, schizoid, and schizotypal personality disorders. People diagnosed as having *schizotypal personality disorder,* for example, display some of the peculiarities seen in schizophrenia but are not disturbed enough to be labeled as schizophrenic. Rather than hallucinating, these people may report "illusions" of sights or sounds. They may also exhibit "magical

personality disorders Long-standing, inflexible ways of behaving that create a variety of problems.

TABLE 15.5 Personality Disorders

Here are brief descriptions of the ten personality disorders listed on Axis II of *DSM-IV-TR*.

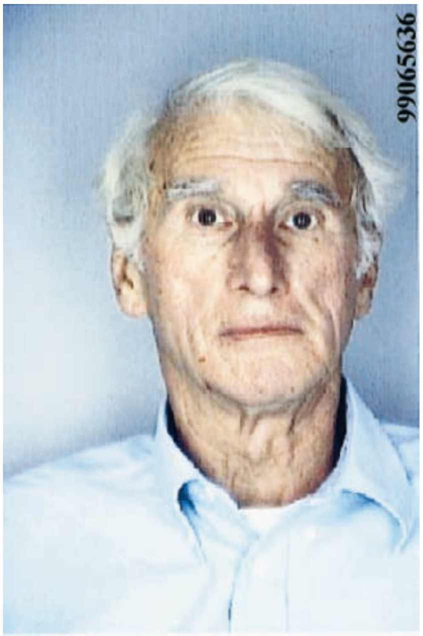
	Type	Typical Features
Cluster A (odd-eccentric)	Paranoid	Suspiciousness and distrust of others, all of whom are assumed to be hostile
	Schizoid	Detachment from social relationships; restricted range of emotion
	Schizotypal	Detachment from, and great discomfort in, social relationships; odd perceptions, thoughts, beliefs, and behaviors
Cluster B (dramatic-erratic)	Histrionic	Excessive emotionality and preoccupation with being the center of attention; emotional shallowness; overly dramatic behavior
	Narcissistic	Exaggerated ideas of self-importance and achievements; preoccupation with fantasies of success; arrogance
	Borderline	Lack of stability in interpersonal relationships, self-image, and emotion; impulsivity; angry outbursts; intense fear of abandonment; recurring suicidal gestures
	Antisocial	Chronic, remorseless pattern of impulsive, irresponsible, dishonest behavior
Cluster C (anxious-fearful)	Dependent	Helplessness; excessive need to be taken care of; submissive and clinging behavior; difficulty in making decisions
	Obsessive-compulsive	Preoccupation with orderliness, perfection, and control
	Avoidant	Inhibition in social situations; feelings of inadequacy; oversensitivity to criticism

thinking," including odd superstitions or beliefs (such as that they have extrasensory perception or that salt under the mattress will prevent insomnia).

The *dramatic-erratic* cluster—called *cluster B*—includes the histrionic, narcissistic, borderline, and antisocial personality disorders. The main characteristics of *narcissistic personality disorder,* for example, are an exaggerated sense of self-importance, extreme sensitivity to criticism, a constant need for attention, and a tendency to arrogantly overestimate personal abilities and achievements. People displaying this disorder feel entitled to special treatment by others but are markedly lacking in empathy *for* others.

The *anxious-fearful* cluster—*cluster C*—includes dependent, obsessive-compulsive, and avoidant personality disorders. *Avoidant personality disorder,* for example, is similar to social phobia in the sense that people labeled with this disorder tend to be "loners" with a long-standing pattern of avoiding social situations and of being particularly sensitive to criticism or rejection. They want to be with others but are too inhibited.

Personality disorder diagnoses are among the most controversial. The controversy arises partly because people with these diagnoses sometimes produce more



Hillsborough County Sheriff, Tampa, Florida

A Classic Case of Antisocial Personality Disorder

Alfred Jack Oakley meets women through personal ads, claiming to be a millionaire movie producer, pilot, and novelist. In reality, he is a penniless con artist who uses smooth talk and charm to gain the women's trust so he can steal from them. In January 2000, after being convicted of stealing a Florida woman's Mercedes, Oakley complimented the prosecutor's skills and the jury's wisdom and claimed to feel remorseful. The judge appeared to see through this ploy ("I don't believe there is a sincere word that ever comes out of your mouth"), but it was still effective enough to get him probation instead of jail time.

distress in others than in themselves, so the role of social and moral judgment in deciding who is disordered comes into play (Clark, 2006). In addition, the overlap among symptoms of some of the personality disorders makes diagnosis difficult (Widiger, Livesley, & Clark, 2009). Studies that use symptom checklists or other behavioral measures to diagnose these disorders, as well as those that use molecular genetic data, generally identify either three or four clusters, not always what would be expected according to *DSM-IV-TR* (Fossati et al., 2006; Livesley, 2005). Some critics have suggested that there is gender bias in the application of diagnoses—pointing to the fact that women are labeled as borderline much more often than men, while men are labeled as antisocial more often than women (Bjorklund, 2006; Boggs et al., 2009). Even the stability of personality disorders over the lifetime has been questioned (Durbin & Klein, 2006). Some aspects of personality disorder diagnoses may be revised in *DSM-V,* but as yet there is no strong consensus about what changes should be made.

From the perspective of public welfare and safety, the most serious, costly, and intensively studied personality disorder is **antisocial personality disorder (APD)**. It is marked by a long-term pattern of irresponsible, impulsive, dishonest, unscrupulous, and even criminal behavior beginning in childhood or early adolescence (Washburn et al., 2007). In the 1800s, this pattern was called *moral insanity* because the people displaying it appear to have no morals or common decency. Later the term *sociopath* or *psychopath* was applied to individuals who display shallow emotions, lack of empathy, and superficial charm and who callously violate social norms (Coid & Ullrich, 2010; Hare & Newmann, 2009). The current "antisocial personality" label used in *DSM-IV-TR* more accurately portrays people displaying the disorder as troublesome and sometimes dangerous but not "insane" by the legal standards we will discuss shortly. About 3 percent of men and about 1 percent of women in the United States fall into the APD category (American Psychiatric Association, 2000; Hodgins, 2007).

At their least troublesome, people exhibiting antisocial personality disorder are a nuisance. They can be charming, intelligent "fast talkers" who borrow money and fail to return it. They can be arrogant and self-centered manipulators who con people into doing things for them, usually by lying and taking advantage of the decency and trust of others. At their most troublesome, people with this disorder are criminals, sometimes violent ones. Persistent violent offenders, most of whom have APD, make up less than 5 percent of the male population, but they commit over 50 percent of violent crimes (Hodgins, 2007). A hallmark of people with APD is a lack of anxiety, remorse, or guilt, whether they have wrecked a borrowed car or killed an innocent person (Gray et al., 2003; Hare & Newmann, 2009). No method has yet been found for permanently altering antisocial personality disorder (Rice, 1997). Research suggests that the best hope for dealing with antisocial personalities is to identify them early, before the most treatment-resistant traits are fully developed (Compton et al., 2005; Crawford, Cohen, & Brooks, 2001; Diamantopoulou, Verhulst, & van der Ende, 2010). Fortunately, these individuals tend to become less active and dangerous after the age of 40 or so (Stoff, Breiling, & Maser, 1997).

Perhaps you are wondering whether terrorists and suicide bombers should be classified as antisocial personalities—after all, they exhibit violent and disruptive behavior in the extreme. Some terrorists do exhibit the characteristics of antisocial personality disorder, but most do not (Martens, 2004). Acts of terrorism might better be explained from the perspective of social and political psychology—terrorists are spurred to take extreme destructive measures by political and religious ideologies during intense group conflict (Saucier et al., 2009). In short, the psychology of group conflict and war might better explain the terrorism of today, just as it might have explained the terrifying behavior of Japanese kamikaze pilots during World War II.

There are numerous theories about the causes of antisocial personality disorder. Some studies suggest a genetic predisposition (Arseneault et al., 2003; Larsson, Andershed, & Lichtenstein, 2006). Genes appear implicated in nearly all disorders; however, the genetic contribution to antisocial behaviors that begin in adolescence

antisocial personality disorder (APD) A personality disorder involving impulsive, selfish, unscrupulous, and even criminal behavior.

or adulthood is modest at best. In contrast, antisocial activity that emerges in early childhood appears to have a stronger genetic component (Arseneault et al., 2003). Genes may influence brain development; reduced brain size and reductions in the amygdala and hippocampal regions are associated with antisocial personality (Craig et al., 2009; van Goozen et al., 2007; Yang et al., 2009). Genes may also contribute to chronic underarousal of both the autonomic and central nervous systems (Crozier et al., 2008; Kiehl et al., 2006; Narayan et al., 2007; Raine et al., 2005). This underarousal may render people less sensitive to punishment and more likely to seek exciting stimulation than is normally the case (Birbaumer et al., 2005; Fowles & Dindo, 2009; Gao et al., 2010).

Other evidence suggests more specific information-processing defects. For example, people diagnosed with antisocial personality disorder perform less well than others do on neuropsychological tests of the ability to make plans (Dolan & Park, 2002). There seem to be specific problems, too, in the processing of fear-related information among people whose symptoms of antisocial personality disorder include extreme emotional detachment (Levenston et al., 2000; Patrick, Bradley, & Lang, 1993). In one study, film clips of delinquent acts were shown to young men with antisocial personality and to non-APD males. The APD males reported lower levels of guilt and fear and higher levels of excitement and happiness while watching (Cimbora & McIntosh, 2003). This diminished responsiveness may be partly explained by a finding that, compared to those without APD, antisocial adolescents have more difficulty simply remembering emotional material (Dolan & Fullam, 2006). Deficits in the ability to encode, recall, and respond to emotional material might help explain the apparent "fearlessness" (and foolishness) of some of their behavior, as well as their insensitivity to other people's emotions (Visser et al., 2010).

Broken homes, rejection by parents, poor discipline, lack of good parental models, lack of attachment to early caregivers, impulsivity, conflict-filled childhoods, and poverty have all been suggested as psychological and social factors contributing to the development of antisocial personality disorder (Caspi et al., 2004; Lahey et al., 1995; Lyman & Gudonis, 2005; Tremblay et al., 1994). The biopsychosocial model suggests that antisocial personality disorder results when these psychosocial and environmental conditions interact with genetic predispositions to low arousal and the sensation seeking and impulsivity associated with it (Diamantopoulou, Verhulst, & van der Ende, 2010; Gray et al., 2003; Rutter, 1997).

FOCUS ON **RESEARCH METHODS**

Exploring Links Between Child Abuse and Antisocial Personality Disorder

One of the most prominent environmental factors associated with the more violent forms of antisocial personality disorder is the experience of abuse in childhood (MacMillan et al., 2001). However, most of the studies that have found a relationship between childhood abuse and APD were based on potentially biased reports (Monane, Leichter, & Lewis, 1984; Rosenbaum & Bennett, 1986). People with antisocial personalities—especially those with criminal records—are likely to make up stories of abuse in order to shift blame for their behavior onto others. Even if these people's reports were accurate, however, most of the studies lacked a control group of people from similar backgrounds who were not antisocial. Because of this research design flaw, it is virtually impossible to separate the effects of reported child abuse from the effects of poverty or other factors that may also have contributed to the development of APD.

What was the researcher's question?

Can childhood abuse cause antisocial personality disorder? To help answer this question and to correct some of the flaws in earlier studies, Cathy Widom (1989) used a prospective research design, first finding cases of childhood abuse and then looking for the effects of that abuse on adult behavior.

How did the researcher answer the question?

Widom began by identifying 416 adults whose backgrounds included official records of having been physically or sexually abused before the age of 11. She then explored the stories of these people's lives, as told in police and school records, as well as in two-hour diagnostic interviews. To reduce experimenter bias and distorted reporting, Widom ensured that the interviewers were unaware of the purpose of the study and that the respondents were told only that the researchers wanted to learn about people who had grown up in a midwestern U.S. metropolitan area in the late 1960s and early 1970s. Widom also selected a comparison group of 283 people who had no history of abuse but who were similar to the abused sample in terms of age, gender, ethnicity, hospital of birth, schools attended, and area of residence. Her goal was to obtain a nonabused control group that had been exposed to approximately the same environmental risk factors and socioeconomic conditions as the abused children.

What did the researcher find?

First, Widom (1989) tested the hypothesis that exposure to abuse in childhood is associated with criminality or violence in later life. She found that 26 percent of the abused youngsters went on to commit juvenile crimes, 29 percent were arrested as adults, and 11 percent committed violent crimes. These percentages were significantly higher than the figures for the nonabused group. The association between criminality and abuse was stronger for males than for females and stronger for African Americans than for European Americans. And overall, victims of physical abuse were more likely than victims of sexual abuse to commit violent crimes as adults.

Next, Widom tested the hypothesis that childhood abuse is associated with the development of antisocial personality disorder (Luntz & Widom, 1994). She found that the abused group exhibited a significantly higher rate of antisocial personality disorder (13.5 percent) than the comparison group (7.1 percent). The apparent role of abuse in antisocial personality disorder was particularly pronounced in men, and it remained strong even when other factors—such as age, ethnicity, and socioeconomic status—were accounted for in the statistical analyses. It is interesting to note that one other factor—failure to graduate from high school—was also strongly associated with the appearance of antisocial personality disorder, whether or not childhood abuse had occurred.

What do the results mean?

Widom's research supported earlier studies in finding an association between childhood abuse and criminality, violence, and antisocial personality disorder. Further, although her study did not permit a firm conclusion that abuse alone causes APD, the data from its prospective design added strength to the argument that abuse may be an important causal factor (Widom, 2000). This interpretation is supported by the results of research by other investigators (Dudeck et al., 2007; Jaffee et al., 2004). Finally, Widom's work offers yet another reason—as if more reasons were needed—why it is so important to prevent the physical and sexual abuse of children. The long-term consequences of such abuse can be tragic not only for its immediate victims but also for those victimized by the violence, criminal actions, and antisocial behavior perpetrated by some abused children as they grow up (Weiler & Widom, 1996; Widom, Czaja, & Dutton, 2008).

What do we still need to know?

Widom's results suggest that one or more of the factors leading teenagers to drop out (or be thrown out) of high school might encourage the development of antisocial personality disorder even in children who were not abused. Some of her more recent work suggests, too, that exposure to poverty and other stressors can be as important as abuse in promoting APD (Horwitz et al., 2001). Further research is needed to discover whether APD stems from abuse itself, from one of the factors accompanying it, or from some other specific combination of known and still-unknown environmental and genetic risk factors (Beach et al., 2010). The importance of combined and interacting risk factors is suggested by the fact that abuse is often part of a larger pool of experiences, such as exposure to deviant models, social rejection, and poor supervision.

In fact, another of Widom's more recent studies (Horwitz et al., 2001) supported the conclusion that childhood abuse increases the likelihood of encountering later stressful life events and that it is some of these events that lead to an increased risk of antisocial personality disorder. In other words, childhood abuse might create general vulnerability for a variety of psychological disorders and life stressors (Scott, Smith, & Ellis, 2010), but the chain of events that promote the development of any particular disorder, such as antisocial personality disorder, are not yet fully understood.

We need to know more, too, about why such a small percentage of the abused children in Widom's sample displayed violence, criminal behavior, and antisocial personality disorder. These results raise the question of what genetic characteristics or environmental experiences serve to protect children from at least some of the devastating effects of abuse (Flores, Cicchetti, & Rogosch, 2005; Rind & Tromovitch, 1997; Rind, Tromovitch, & Bauserman, 1998; Widom et al., 2007). As described in the chapter on human development, some clues have already been found (Caspi et al., 2002; Kim-Cohen & Gold, 2009; Wills et al., 2001), but a better understanding of these protective elements is needed if there are to be effective programs for the prevention of antisocial personality disorder.

A Sampling of Other Psychological Disorders

The disorders described so far represent some of the most prevalent and socially disruptive psychological problems encountered in cultures around the world. Several others are mentioned in other chapters. For example, intellectual disability is covered in the chapter on cognitive abilities; posttraumatic stress disorder is described in the chapter on health, stress, and coping; and sleep disorders are discussed in the chapter on consciousness. Here we consider two other significant psychological problems: disorders of childhood and substance-related disorders.

Psychological Disorders of Childhood

The physical, cognitive, emotional, and social changes seen in childhood—and the stress associated with them—can cause or worsen psychological disorders in children. Stress can do the same in adults, but childhood disorders are not just miniature versions of adult psychopathology. Because children's development is still incomplete and because their capacity to cope with stress is limited, children are often vulnerable to special types of disorders. *DSM-IV-TR* lists over two dozen Axis I disorders seen in infants, children, and adolescents, but the majority of childhood behavior problems can be placed in two broad categories: externalizing disorders and internalizing disorders (Phares, 2008).

The *externalizing,* or *undercontrolled,* category includes behaviors that are particularly disturbing to people in the child's environment. Lack of control shows up as *conduct disorders* in about 2 to 9 percent of children and adolescents, mostly boys, and appears most frequently at around 11 or 12 years of age (Merikangas et al., 2010; Nock et al., 2006). Conduct disorders are characterized by a relatively stable pattern of aggression, disobedience, destructiveness, inappropriate sexual activity, academic failure, and other problematic behaviors (Kalb & Loeber, 2003; Petitclerc & Tremblay, 2009). Often these behaviors involve criminal activity, and they may signal the development of antisocial personality disorder (Loeber & Stouthamer-Loeber, 1998; Lyman & Gudonis, 2005).

There may be a genetic predisposition toward externalizing disorders, including conduct disorders that begin in childhood and progress into adulthood (Larsson, Andershed, & Lichtenstein, 2006; Van Hulle et al., 2009). For example, many children who display conduct disorder have parents with antisocial personality disorder (Gelhorn et al., 2005). Further, externalizing disorders are especially likely to appear in children with temperamentally high activity levels and lack of concern for the feelings of other people (Anastassiou-Hadjicharalambous & Warden, 2008; Mesman & Koot, 2000). There is no doubt, however, that environmental and parenting factors also shape these children's behavior and that these factors interact with genetic factors (Hanish et al., 2005; Laird et al., 2001; Leve, Kim, & Pears, 2005; Scourfield et al., 2004).

Another kind of externalizing problem, *attention deficit hyperactivity disorder* (*ADHD*), is seen in up to 8 percent of children, mainly boys (and in about 4 percent of adults, mainly men; Bloom & Cohen, 2007; Merkangas et al., 2010). A diagnosis of ADHD is given to children who are more impulsive or more inattentive than other children their age (Nigg, 2001; Wolraich et al., 2005). *DSM-IV-TR* lists three subtypes of this disorder: primarily inattentive, primarily impulsive, and combined (both inattentive and impulsive). As the name implies, many of these children are *hyperactive*. That is, they have great difficulty sitting still or otherwise controlling their physical activity. Their impulsiveness and lack of self-control contribute to significant impairments in learning and to an astonishing ability to annoy and exhaust the people around them. Children diagnosed with ADHD also tend to perform poorly on tests of attention, memory, decision making, and other information-processing tasks. As a result, ADHD is being increasingly viewed as a neurological condition rather than just "bad behavior" (Halperin & Schulz, 2006; Konrad et al., 2006; Krain & Castellanos, 2006).

ADHD may result from a genetic predisposition. Some studies suggest that the genes involved may be those that regulate dopamine, a neurotransmitter important in the functioning of the attention system (Bush, 2010; Gilden & Marusich, 2009; Waldman & Gizer, 2006). Other factors, including brain damage, poisoning from lead or other household substances, and low birth weight, may also play causal roles (Hudziak et al., 2005; Linnet et al., 2003; Mick et al., 2002; Nikolas & Burt, 2010). In some cases, problem s in parenting may increase the risk for this disorder (Clarke et al., 2002). Exactly how all these factors combine is still not clear (Nigg, 2010). Also uncertain is exactly what constitutes hyperactivity. Cultural standards about acceptable activity levels in children vary, so a "hyperactive" child in one culture might be considered merely "active" in another. In fact, when mental health professionals from four cultures used the same rating scales to judge the presence and severity of hyperactivity in a videotaped sample of children's behavior, the Chinese and Indonesians rated the children as significantly more hyperactive than their American and Japanese colleagues did (Mann et al., 1992; see also Jacobson, 2002). And as mentioned earlier, there is evidence that African American children are diagnosed with ADHD only about two-thirds as often as European American children, even when they have at least as many symptoms (Miller, Nigg, & Miller, 2009). Such findings remind us again that sociocultural factors can be important determinants of what is acceptable—and hence what is abnormal—in various parts of the world.

Active or Hyperactive?

TRY THIS Normal behavior for children in one culture can be considered hyperactive in other cultures. Do people in the *same* culture disagree on what is hyperactive? To find out, ask two or three friends to join you in observing a group of children at a playground, a schoolyard, a park, or some other public place. Ask your friends to privately identify which children they would label as "hyperactive," and then count how many of their choices agree with yours and with each other's. With many children in many cultures showing high activity levels, some observers wonder about the validity of the ADHD diagnosis and especially about the wisdom of medicating the children who receive it (Merikangas et al., 2010).

A second broad category of child behavior problems involves *internalizing,* or *overcontrol.* Children in this category experience significant distress, especially depression and anxiety, and may be socially withdrawn (Luby, 2010). Those displaying *separation anxiety disorder,* for example, constantly worry that they will be lost, kidnapped, or injured or that some harm may come to a parent (usually the mother). The child clings desperately to the parent and becomes upset or sick at the prospect of any separation. Refusal to go to school (sometimes called "school phobia") is often the result. Children who are shy or withdrawn are at a higher risk than others for internalizing disorders, but these problems are also associated with environmental factors, including being rejected by peers and (especially for girls) being raised by a single parent (Phares, 2008; Prinstein & La Greca, 2002).

A few childhood disorders, such as *pervasive developmental disorders,* do not fall into either the externalizing or internalizing category. Children diagnosed with these disorders show severe problems in communication and impaired social relationships. They also often display repetitive, stereotyped behaviors and unusual preoccupations and interests (American Psychiatric Association, 2000). The disorders in this group, also known as *autistic spectrum disorders* (*ASD*), share many of these core symptoms, although the severity of those symptoms may vary (Çeponien et al., 2003; Constantino & Todd, 2003). Estimates of the prevalence of ASD in the United States range from 10 to 20 children per 10,000 births (Bryson & Smith, 1998; Filipek et al., 1999) to as high as 110 per 10,000 (Chakrabarti & Fombonne, 2001). If, as recent data suggest, the actual rate is nearer the high end of this range, nearly 700,000 children could be affected (Williams et al., 2008). ASD is diagnosed in boys four times as often as in girls and more often in European American children than in other groups (Kogan et al., 2009). Some of these children have *autistic disorder,* which can be the most severe of the group. The earliest signs of autistic disorder usually appear within the first thirty months after birth, as these babies show little or no evidence of forming an attachment to their caregivers. Language development is seriously disrupted in most of these children; half of them never learn to speak at all. They have great difficulty engaging in tasks that require shared attention, and they often focus on nonsocial aspects of human interaction, such as clothing, rather than on social aspects such as eye contact, facial expression, and tone of voice (Klin et al., 2002). Those who display high-functioning autism or a less severe autistic spectrum disorder called *Asperger's syndrome* (also known as *Aspberger's disorder*) have impaired relationships, engage in repetitive behaviors, and may memorize arcane facts or activities (such as sports scores or ZIP codes), but they show few severe cognitive deficits and are able to function adaptively and, in some cases, independently as adults (e.g., Grandin, 1996; Shore, 2003).

Possible biological roots of autistic disorder include genetic factors (Freitag, 2007; Gupta & State, 2007; St. Pourcain et al., 2010 Vorstman et al., 2006; Weiss & Arking, 2009) and neurodevelopmental abnormalities affecting language and communication (Akshoomoff, 2005; Belmonte et al., 2004; Grossberg & Seidman, 2006; Minshew & Williams, 2007). Researchers studying these biological factors have recently become interested in the activity of mirror neurons in the brain. As described in the chapter on biological aspects of psychology, these neurons are activated when we see other people's actions, such as smiling, frowning, or showing disgust. Because they are in the areas of our own brain that control these same actions, activity in mirror neurons help us understand how the other person might be feeling and empathize with those feelings. The functioning of such neurons appears disturbed in people with autism, partly explaining why these individuals seem to operate with little appreciation for what others might be thinking or feeling (Welsh et al., 2009; Williams et al., 2006). Other problems have been found in the brains of children with autism, mainly in the prefrontal cortex and in the corpus callosum (which connects the two cerebral hemispheres). These problems may impair the communication among brain areas that is necessary for normal social interaction and language (Mitchell et al., 2009). Hypotheses that autistic disorder is caused by having cold and unresponsive parents or by injections of measles, mumps, rubella (MMR) vaccine have been rejected by the results of scientific research (e.g. Doja & Roberts, 2006).

Disorders of childhood differ from adult disorders not only because the patterns of behavior are distinct but also because their early onset disrupts development. To take one example, children whose separation anxiety causes spotty school attendance may not only fall behind academically but also fail to form the relationships with other children that promote normal social development (Wood, 2006). Some children never make up for this deficit. They may drop out of school and risk a life of poverty, crime, and violence. Moreover, children are dependent on others to obtain help for their psychological problems, but all too often those problems may go unrecognized or untreated. For some, the long-term result may be adult forms of mental disorder.

Substance-Related Disorders

Childhood disorders, especially externalizing disorders, often lead to *substance-related disorders* in adolescence and adulthood. *DSM-IV-TR* defines **substance-related disorders** as the use of psychoactive drugs for months or years in ways that harm the user or others. These disorders create major political, economic, social, and health problems worldwide. The substances involved most often are alcohol and other

substance-related disorders Problems involving the use of psychoactive drugs for months or years in ways that harm the user or others.

CNS depressant drugs (such as barbiturates), opiates (such as heroin), CNS stimulating drugs (such as cocaine or amphetamines), and hallucinogenic drugs (such as LSD). About half the world's population uses at least one psychoactive substance, and about two-thirds of U.S. citizens report that problems related to alcohol or drug use have affected them, their families, or their close friends (Leamon, Wright, & Myrick, 2008).

One effect of using some substances (including alcohol, cocaine, heroin, and amphetamines) is **addiction**, a physical need for the substance. *DSM-IV-TR* calls addiction *physiological dependence.* Usually, addiction is evident when the person begins to need more and more of a substance to achieve the desired state. This condition is called building a *drug tolerance.* When addicted people stop using the substance, they experience painful, often terrifying, and potentially dangerous *withdrawal symptoms* as the body tries to readjust to a substance-free state. People can also display *psychological dependence,* sometimes called *behavioral dependence.* For these people, a drug has become their primary source of reward, and their lives essentially revolve around getting and using it. People who are psychologically dependent on a drug often display problems that are at least as serious as those of people who are physiologically addicted, and the problems are sometimes more difficult to treat.

Even when use of a drug does not lead to psychological or physiological dependence, some people may use it in a way that is harmful to themselves or others. For example, they may rely on the drug to bolster self-confidence or to avoid depression, anger, fear, or other unpleasant feelings. However, the drug effects these people seek may also impair their ability to hold a job, care for their children, or drive safely. This pattern of behavior, defined in *DSM-IV-TR* as *substance abuse,* causes significant social, legal, and interpersonal problems.

In short, substance-related disorders can be extremely serious, even when they do not involve addiction. In the chapter on consciousness, we describe how consciousness can be affected by a wide range of psychoactive drugs. Here we focus more specifically on the problems associated with the use and abuse of alcohol, heroin, and cocaine.

Alcohol Use Disorders According to a large national survey, the twelve-month prevalence of alcohol abuse, as defined in *DSM-IV-TR,* was 3.1 percent of adults (Kessler & Wang, 2008). *Alcohol abuse* is characterized by a pattern of continuous or intermittent drinking that may lead to *alcohol dependence,* an addiction that almost always causes severe social, physical, and other problems (an additional 1.3 percent of U.S. adults fall into the dependent category). Males outnumber females in this category by about three to one, although the problem is on the rise among women and among teenagers of both sexes (Grucza et al., 2008). Abuse is greater among European Americans and American Indians than among African Americans and Hispanics; it is lowest among Asians (Chassin, Pitts, & Prost, 2002; Grant et al., 2004; Substance Abuse and Mental Health Services Administration, 2007). Prolonged overuse of alcohol can have serious consequences, including reduced cognitive abilities, impaired academic performance, life-threatening liver damage, vitamin deficiencies that can lead to an irreversible brain disorder called *Korsakoff's psychosis* (severe memory loss), and many other physical ailments. Many of these adverse effects appear to be due to the fact that excessive alcohol consumption causes deterioration in several brain areas (Hommer et al., 2001; Pfefferbaum et al., 2001).

Alcohol dependence or abuse, commonly referred to as **alcoholism**, has been implicated in 40 to 50 percent of all automobile accidents, murders, and rapes (Butcher, Mineka, & Hooley, 2010). Alcohol abuse also figures prominently in domestic violence, including child abuse, and in elevated rates of hospitalization and absenteeism from work, resulting in total costs to society of over $180 billion each year in the United States alone (Keller et al., 2009; National Institute on Alcohol Abuse and Alcoholism [NIAAA], 2001). It is estimated that about half of U.S. adults have a close relative who is an active or recovering alcoholic and that about 25 percent of children are exposed to adults who display alcohol abuse or dependence (NIAAA, 2001). Children growing up in families in which one or both parents abuse alcohol are at increased risk for developing a host of mental disorders, including substance abuse disorders

addiction Development of a physical need for a psychoactive drug.

alcoholism A pattern of drinking that may lead to addiction and almost always causes severe social, physical, and other problems.

(Hoffmann & Cerbone, 2002; Odgers et al., 2008). And as described in the chapter on human development, children of mothers who abused alcohol during pregnancy may be born with fetal alcohol syndrome.

The biopsychosocial model suggests that alcohol use disorders stem from a combination of genetic characteristics (including inherited aspects of temperament such as impulsivity and emotionality) and what people learn in their social and cultural environments (Elkins et al., 2006; Lovallo et al., 2006; Ray et al., 2010). For example, children of people with alcoholism are more likely than others to become alcoholics themselves; and if the children are identical twins, both are at increased risk for alcoholism, even when raised apart (Volk et al., 2007). It is still unclear just what might be inherited or which genes are involved. One possibility involves inherited abnormalities in the brain's neurotransmitter systems or in the body's metabolism of alcohol (Martinez et al., 2005; Nurnberger et al., 2001; Petrakis et al., 2004). Males with alcoholism do tend to be less sensitive than other people to the effects of alcohol—a factor that may contribute to greater consumption (Pollack, 1992; Schuckit, 1998). Now that the human genome has been decoded, researchers are focusing on specific chromosomes as the possible locations of genes that predispose people to—or protect them from—the development of alcoholism (Cheng et al., 2004; NIAAA, 2000, 2001; Wall et al., 2005). However, the genetics of addiction is complex, and there are likely multiple pathways to alcoholism (Crabbe, 2002; Higuchi, Matsushita, & Kashima, 2006).

As with other disorders, alcoholism probably arises as many genes interact with one another and with environmental events, including parental influences (Duncan et al., 2006; Kaufman et al., 2007). For example, one study found that the sons of identical twins were at elevated risk for alcoholism if their own father was an alcoholic but not if the father's identical twin was (Jacob et al., 2003). Something in these boys' nonalcoholic family environment had apparently moderated whatever genetic tendency toward alcoholism they might have inherited. Youngsters typically learn to drink by watching their parents and their peers. These observations help shape their expectations, such as that alcohol will make them feel good and help them cope with stressors (Schell et al., 2005). But if drinking becomes a person's main coping strategy, alcohol use can become abuse and ultimately addiction (NIAAA, 2001). The importance of social and cultural learning is supported by evidence that alcoholism is more common among ethnic and cultural groups (such as the Irish and English) in which frequent drinking tends to be socially reinforced than among groups (such as Jews, Italians, and Chinese) in which anything beyond moderate drinking tends to be discouraged (Gray & Nye, 2001; Wilson et al., 1996). Moreover, variations in social support for drinking can result in differing consumption patterns within a cultural group. For example, one study found significantly more drinking among Japanese men living in Japan (where social norms for males' drinking are quite permissive) than among those living in Hawaii or California, where excessive drinking is less strongly supported (Kitano et al., 1992). Learning would also help explain why rates of alcoholism are higher than average among bartenders, cocktail servers, and others who work where alcohol is available and drinking is socially reinforced or even expected (Fillmore & Caetano, 1980). (Of course, it is also possible that attraction to alcohol led some of these people into such jobs in the first place.)

Heroin and Cocaine Dependence Like people with alcoholism, heroin and cocaine addicts suffer many serious physical problems, both as a result of the drugs themselves and of the poor eating and other unhealthy habits associated with drug use. The risk of death from an overdose, contaminated drugs, or AIDS (contracted through blood in shared needles), as well as from suicide, is also always present. Dependence on these drugs tends to be more prevalent among males, especially young males (Compton et al., 2007; Warner et al., 1995).

Continued use or overdoses of cocaine can cause problems ranging from nausea and hyperactivity to paranoid thinking, sudden depressive "crashes," and even death. Cocaine use has been on the decline since 1985, but it is still a serious problem. Surveys indicate that 7.7 percent of high school seniors in the United States have used cocaine at some time in their lives, and millions more teens and adults still use it on occasion (Johnston et al., 2004). The widespread availability of crack, a powerful and relatively cheap form of cocaine, has made it one of the most dangerous and addicting of all drugs. Pregnant women who use cocaine are much more likely than nonusers to lose their babies through spontaneous abortion, placental detachment, early fetal death, or stillbirth.

Addiction to heroin and cocaine appears in about 4 percent of the adult population in the United States (Compton et al., 2005). It occurs largely through a biological process brought on by the physiological effects of the drugs (Kalivas & Volkow, 2005; Phillips et al., 2003). Explaining why people start using them is more complicated. Beyond the obvious and immediate pleasure that these drugs provide, the causes of initial drug abuse are less well established than the reasons for alcohol abuse. One line of theorizing suggests that there might be a complex genetic predisposition toward behavioral compulsions that predispose some people to abuse many kinds of drugs (Crabbe, 2002; Koob & Volkow, 2010; Kreek et al., 2005). One study supporting this possibility found a link between alcoholism in biological parents and drug abuse in the sons they had given up for adoption (Cadoret et al., 1995).

A number of psychological and environmental factors have also been proposed as promoting initial drug use (Alessi et al., 2002; Brems & Namyniuk, 2002; Hoffmann & Cerbone, 2002). These include seeing parents using drugs, being abused in childhood, using drugs to cope with stressors or to ease anxiety or depression, associating drug use with pleasant experiences, seeking popularity, caving in to peer pressure, and thrill seeking (Alessi et al., 2002; Baker et al., 2004; Dube et al., 2003; Putnam, 2003; Reed, Anthony, & Breslau, 2007). Research has not yet established why continued drug use occurs in some people and not in others, but again, it is likely that a biological predisposition sets the stage on which specific psychological processes and stressors play out their roles in specific social and cultural contexts (Hammen, 2009; Kreek et al., 2005).

Mental Illness and the Law

> Cheryl was barely 20 when she married Glen, a graduate student in biology. They moved into a large apartment complex near the university and within three years had two sons. Cheryl's friends had always been impressed by the attention and affection she showered on her boys; she seemed to be the ideal mother. She and Glen had serious marital problems, however, and she felt trapped and unhappy. One day, Glen came home to find that Cheryl had stabbed both children to death. At her murder trial, she was found not guilty by reason of insanity and was placed in a mental institution.

This verdict reflects U.S. laws and rules that protect people with severe psychological disorders when they are accused of crimes (Cassel & Bernstein, 2007). Similar laws and rules are in effect in many other countries. The protection takes two forms.

First, under certain conditions, people designated as mentally ill may be protected from prosecution. If, at the time of their trial, individuals accused of a crime are unable to understand the proceedings and charges against them or to assist in their own defense, they are declared to be *mentally incompetent* to stand trial. In such cases, defendants are sent to a mental institution until they are judged to have become mentally competent. If still not competent after a court-specified period—two years, in most cases—a defendant may be ruled permanently ineligible for trial and either committed in civil court to a mental institution or released. Release is rare, however, because competency to stand trial requires only minimal mental abilities. If drugs can produce even temporary mental competence, the defendant will usually go to trial (Nietzel, 1999).

Second, mentally ill defendants may be protected from punishment. In most U.S. states, they may be judged *not guilty by reason of insanity* if, at the time of the crime, mental illness prevented them from understanding what they were doing, knowing that what they were doing was wrong, or resisting the impulse to do wrong. The first two of these criteria—understanding the nature or wrongfulness of an act—are "cognitive"

Assessment of Mental Competence

APPLYING PSYCHOLOGY Andrea Yates admitted to drowning her five children in the bathtub of her Houston, Texas, home in 2001. She had twice tried to kill herself in previous years, and she was reportedly depressed at the time of the murders. Accordingly, she pleaded not guilty by reason of insanity. The court's first step in deciding her fate was to confine her in a mental institution for assessment of her mental competency to stand trial. Following testimony of psychologists who examined her, she was found competent, tried, and sentenced to life in prison. Her conviction was overturned on appeal, though, and at a second trial in 2006, she was found not guilty by reason of insanity and committed to a mental hospital.

criteria known as the M'Naghton rule. This rule stems from an 1843 case in England in which a man named Daniel M'Naghton, upon hearing "instructions from God," tried to kill British prime minister Robert Peel. He was found not guilty by reason of insanity and put into a mental institution for life. The third criterion, which is based on a defendant's emotional state during a crime, is known as the *irresistible-impulse test*. All three criteria were combined in a rule proposed by the American Law Institute (ALI) in 1962 and now followed by about one-third of the U.S. states: "A person is not responsible for criminal conduct if at the time of such conduct as a result of mental disease or defect he lacks substantial capacity either to appreciate the criminality (wrongfulness) of his conduct or to conform his conduct to the requirements of law" (p. 66).

In 1984, after John Hinckley Jr. was found not guilty by reason of insanity under the ALI rule for his attempted assassination of President Ronald Reagan, the U.S. Congress passed the Insanity Defense Reform Act, which eliminated the irresistible-impulse criterion from the definition of insanity in federal cases. About 75 percent of the U.S. states have passed similar or related reform laws (Giorgi-Guarnieri et al., 2002). In about half the states, these laws require the use of some version of the narrower M'Naghton rule (American Psychiatric Association, 2003). These laws highlight the fact that *insanity* is a legal term, not a psychiatric diagnosis; it does not appear in *DSM-IV-TR* (Cassel & Bernstein, 2007). When defendants plead insanity, judges and juries must decide whether or not these people understood what they were doing or had control over their actions and hence whether or not they should be held responsible for their criminal acts. Defendants who are judged not guilty by reason of insanity and who still display a psychological disorder are usually required to receive treatment, typically through commitment to a hospital, until judged to be cured or no longer dangerous.

Insanity rules have been faulted on several grounds. Some critics argue that everyone, even people who meet legal criteria for insanity, should be held responsible for their actions and punished for their crimes. Others point out significant problems in the implementation of insanity rules. For one thing, different experts often give conflicting, highly technical testimony about a defendant's sanity at the time of a crime. (In the case mentioned at the beginning of this section, one expert said Cheryl was sane; another concluded she was insane.) Jurors are then left in the difficult position of deciding which expert to believe and what to make of the experts' diagnostic judgments. Their task is complicated by the fact that people with mental disorders—even those as severe as schizophrenia—are still capable of some rational decision making and of controlling some aspects of their behavior (Grisso & Appelbaum, 1995;

Matthews, 2004). Concern over such problems has led four U.S. states—Montana, Idaho, Utah, and Kansas—to abolish the insanity defense. Other states have tried less extreme reforms. In thirteen states, it is possible for juries to find defendants *guilty but mentally ill*. These defendants still serve a sentence, and although they are supposed to receive treatment while confined, they seldom do (Cassel & Bernstein, 2007). A second reform already noted is that federal courts no longer use the irresistible-impulse criterion in defining insanity. Third, federal courts and some state courts now require defendants to prove that they were insane at the time of their crime, rather than requiring the prosecution to prove that the defendants were sane.

Does the insanity defense allow lots of criminals to "get away with murder"? No. Although certain high-profile cases might suggest otherwise, the insanity plea is used in fewer than one of every two hundred felony cases in the United States—usually when the defendant displays severe psychological disorder—and this plea is successful in only two of every thousand attempts (American Psychiatric Association, 2003; Silver, Cirincione, & Steadman, 1994). Further, the few defendants found not guilty by reason of insanity are usually hospitalized for two to nine times as long as they would have spent in prison had they been convicted (Silver, 1995; Steadman, 1993). For example, John Hinckley Jr. has been in Saint Elizabeth's Hospital in Washington, D.C. since 1982, and despite his annual efforts to be released and court approval for longer visits with his mother outside the hospital, he is unlikely to be freed anytime soon.

In summary, society is constantly seeking the proper balance between protecting the rights of defendants and protecting itself from dangerous criminals. In doing so, the sociocultural values that shape views about what is abnormal also influence judgments about the extent to which abnormality should relieve people of responsibility for criminal behavior.

LINKAGES

As noted in the chapter on introducing psychology, all of psychology's many subfields are related to one another. Our discussion of the role of learning principles in the development of phobias illustrates just one way in which the topic of this chapter, psychological disorders, is linked to the subfield of learning (which is the focus of the chapter by that name). The Linkages diagram shows ties to two other subfields as well, and there are many more ties throughout the book. Looking for linkages among subfields will help you see how they all fit together and better appreciate the big picture that is psychology.

Biological Aspects of Psychology

CHAPTER 6
Learning

CHAPTER 14
Personality

SUMMARY

Psychopathology involves patterns of thinking, feeling, and behaving that cause personal distress or that significantly impair a person's social or occupational functioning.

Defining Psychological Disorders

Some disorders show similarity across cultures, but the definition of abnormality is largely determined by social and cultural factors.

What Is Abnormal?

The criteria for judging abnormality include statistical infrequency (a comparison with what most people do), norm violation, and personal suffering. Each of these criteria is flawed to some extent.

Behavior in Context: A Practical Approach

The practical approach to defining abnormality, which considers the content, context, and consequences of behavior, emphasizes the question of whether individuals show impaired functioning in fulfilling the roles appropriate for particular people in particular settings, cultures, and historical eras.

Explaining Psychological Disorders

Abnormal behavior has been attributed, at one time or another, to many different factors, including the action of supernatural forces.

The Biopsychosocial Approach

In today's *biopsychosocial approach,* mental disorders are attributed to the combination and interaction of biological, psychological, and sociocultural factors. Biological factors are emphasized by the *medical model* (also called the *neurobiological model*), which sees psychological disorders as reflecting disturbances in the anatomy and chemistry of the brain and in other biological processes. The causal factors emphasized by the *psychological model* of mental disorders include unconscious conflicts, disruptions in attachment, learning, or maladaptive cognitive schemas. The *sociocultural perspective* focuses on *sociocultural factors* that help define abnormality and influence the form that disorders take in different parts of the world.

Diathesis-Stress as an Integrative Explanation

No single aspect of the biopsychosocial approach can adequately explain all psychological disorders. The *diathesis-stress model* takes into account all the causal factors in that approach by suggesting that biological, psychological, and sociocultural characteristics create predispositions for disorder and that the symptoms of a disorder appear only in the face of sufficient amounts of stress.

Classifying Psychological Disorders

There seems to be a set of behavior patterns that roughly defines abnormality in most cultures. Classifying these patterns helps identify the features, causes, and most effective methods of treating various psychological disorders.

A Classification System: *DSM-IV-TR*

The dominant system for classifying abnormal behavior in North America is the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-IV*) in its most recent text revision (*DSM-IV-TR*). It includes more than three hundred specific categories of mental disorders. As with medical illnesses, categories for psychological disorders are periodically revised as research accumulates.

Evaluating the Diagnostic System

Research on the reliability and validity of *DSM-IV-TR* shows that it is a useful but imperfect classification system.

Anxiety Disorders

Long-standing and disruptive patterns of anxiety characterize *anxiety disorders.*

Types of Anxiety Disorders

The most prevalent type of anxiety disorder is *phobia,* which includes *specific phobias, social phobias,* and *agoraphobia.* Other anxiety disorders are *generalized anxiety disorder,* which involves nonspecific anxiety; *panic disorder,* which brings unpredictable attacks of intense anxiety; and *obsessive-compulsive disorder* (*OCD*), characterized by uncontrollable repetitive thoughts (*obsessions*) and ritualistic actions (*compulsions*).

Causes of Anxiety Disorders

The most influential explanations of anxiety disorders suggest that they may develop through the combination of a biological predisposition for strong anxiety reactions and the impact of fear-enhancing thought patterns and learned anxiety responses.

Somatoform Disorders

Somatoform disorders, including *conversion disorder,* involve physical problems that have no apparent physical cause. Other examples are *hypochondriasis,* an unjustified concern about being ill; *somatization disorder,* in which the person complains of numerous, unconfirmed physical complaints; *somatoform pain disorder,* in which pain is felt in the absence of a known physical cause; and *body dysmorphic disorder,* characterized by intense distress over imagined abnormalities of the skin, hair, face, or other bodily areas.

Dissociative Disorders

Dissociative disorders involve rare conditions such as *dissociative fugue, dissociative amnesia,* and *dissociative identity disorder, or DID* (multiple personality disorder), in which a person suffers memory loss or develops two or more identities.

Affective Disorders

Affective disorders, also known as *mood disorders,* involve extreme moods of long duration that may be inconsistent with events.

Depressive Disorders

Major depression (*major depressive disorder*) is marked by feelings of inadequacy, worthlessness, and guilt; in extreme cases, *delusions* may also occur. *Dysthymic* *disorder* includes similar but less severe symptoms persisting for a long period. Suicide is often related to these disorders.

Bipolar Disorders

Alternating periods of depression and *mania* characterize *bipolar disorders. Cyclothymic personality* (*cyclothymic disorder*), an alternating pattern of less extreme mood swings, is more common.

Causes of Affective Disorders

Affective disorders have been attributed to biological causes such as genetics—which underlie disruptions in neurotransmitter and endocrine systems—and irregularities in biological rhythms. Both loss of significant sources of reward and maladaptive patterns of thinking are among the psychological causes proposed. A predisposition toward some of these disorders appears to be inherited, although their appearance may be determined by a diathesis-stress process.

Schizophrenia

Schizophrenia is perhaps the most severe and puzzling disorder of all.

Symptoms of Schizophrenia

Among the symptoms of schizophrenia are problems in thinking, perception (often including *hallucinations*), attention, emotion, movement, motivation, and daily functioning.

Categorizing Schizophrenia

Although *DSM-IV-TR* lists five major subtypes of schizophrenia (paranoid, disorganized, catatonic, undifferentiated, and residual), many researchers today favor viewing it as a spectrum disorder involving displays of *positive symptoms* (such as hallucinations and disorganized thoughts) and *negative symptoms* (such as lack of speech and restricted emotional expression). Each category of symptoms may be traceable to different causes. Predominantly negative symptoms tend to be associated with more severe disorder and less successful treatment outcomes.

Causes of Schizophrenia

Genetic factors, neurotransmitter problems, abnormalities in brain structure and functioning, and neurodevelopmental abnormalities are biological factors implicated in schizophrenia. Psychological explanations have focused on maladaptive learning experiences and disturbed family interactions. The diathesis-stress approach, often described in terms of the vulnerability model, remains a promising framework for research into the multiple causes of schizophrenia.

Personality Disorders

Personality disorders are long-term patterns of maladaptive behavior that may be disturbing to the person displaying them or to others. Examples include schizotypal, avoidant, narcissistic, and *antisocial personality disorders.*

A Sampling of Other Psychological Disorders

Psychological Disorders of Childhood

Childhood disorders can be categorized as externalizing disorders (such as conduct disorders or attention deficit hyperactivity disorder) and internalizing disorders (in which children show overcontrol and experience distress, as in separation anxiety disorder). Pervasive developmental disorders do not fall into either category and include the autistic spectrum disorders. In autistic disorder, which can be the most severe of these, children show no interest in or attachment to others.

Substance-Related Disorders

Substance-related disorders involving alcohol and other drugs affect millions of people. *Addiction* to, psychological dependence on, or abuse of these substances contributes to disastrous personal and social problems, including physical illnesses, accidents, and crime. Genetic factors may create a predisposition for *alcoholism,* but learning, cultural traditions, and other psychosocial processes are also important. In the case of dependence on heroin and cocaine, stress reduction, imitation, thrill seeking, and parental modeling have been proposed as important causal factors, along with genetics. The exact causes of initial use of these drugs, however, are not fully understood.

Mental Illness and the Law

Current rules protect people accused of crimes from prosecution or punishment if they are mentally incompetent at the time of their trials or if they were legally insane at the time of their crimes. Difficulty in establishing the mental state of defendants and other knotty problems have created dissatisfaction with those rules and prompted a number of reforms, including the "guilty but mentally ill" verdict.

LINKAGES TO FURTHER LEARNING

Now that you have finished reading this chapter, how about exploring some of the topics and information that you found most interesting? Here are some places to start.

Books

Robert L. Spitzer, Michael B. First, Janet B. W. Williams, and Miriam Gibbon, *DSM-IV Casebook: A Learning Companion to the Diagnostic and Statistical Manual of Mental Disorders* (American Psychiatric Press, 1994). A casebook illustrating the disorders listed in the DSM-IV.

Karen Eriksen and Victoria Kress, *Beyond the DSM Story: Ethical Quandaries, Challenges, and Best Practices* (Sage, 2005). A summary of the *DSM* and its problems and alternative approaches.

William Styron, *Darkness Visible* (Vintage, 1992). Depression, suicidality.

Patty Duke, *A Brilliant Madness* (Bantam, 1993). Bipolar disorder.

Vaslav Nijinsky, *The Diary of Vaslav Nijinsky* (Farrar, Straus & Giroux, 1999). Insight into schizophrenia from one of Eugen Bleuler's most famous patients, the Russian ballet dancer.

Jerald J. Kriesman and Hal Straus, *I Hate You—Don't Leave Me: Understanding the Borderline Personality* (Avon, 1991). Descriptions and explanations of borderline behaviors, focusing on conflicted relationships.

Judith Rapoport, *The Boy Who Couldn't Stop Washing* (New American Library, 1997). Obsessive-compulsive disorder.

Joan Acocella, *Creating Hysteria: Women and Multiple Personality Disorder* (Jossey-Bass, 1999). A description of the influence of culture and other social forces in shaping dissociative identity disorder.

Meyer Glantz and Christine Hartel (Eds.), *Drug Abuse: Origins and Interventions* (American Psychological Association, 2000). Information that challenges various myths about drug abuse.

TALKING POINTS

Here are a few talking points to help you summarize this chapter for family and friends without giving a lecture.

1. Though there are many more specific criteria, people are most likely to be diagnosed with a mental disorder when psychological or behavioral problems significantly impair their ability to function in society.
2. Behavior that is considered normal in one culture may be considered abnormal in another.
3. In general, behavior disorders emerge when an inherited predisposition interacts with environmental stress.
4. *DSM-V*, a new and expanded edition of the standard psychiatric diagnosis manual, is scheduled for publication in 2013.
5. Take suicide threats seriously; encourage the person to seek help.
6. Schizophrenia does not involve multiple personalities.
7. *Insanity* is a legal term, not a psychiatric diagnosis.

SUMMARY

Many movies and television dramas include scenes in a psychotherapist's office, but even the best of them tell only part of the story of how psychological disorders can be treated. In this chapter, we describe a wide range of treatment options, from "talking therapy" to prescription drugs. We also summarize the results of research on the effectiveness of treatment and on efforts to prevent psychological disorders.

In the chapter on psychological disorders, we described José, an electronics technician who was forced to take medical leave from his job because of repeated panic attacks (see Table 15.1). After four months of diagnostic testing turned up no physical problems, José's physician suggested that he see a psychologist. José resisted at first, insisting that his condition was not "just in his head," but he eventually began psychological treatment. Within a few months, his panic attacks had stopped, and José had returned to all his old activities. After the psychologist helped him reconsider his workload, José decided to retire from his job in order to pursue more satisfying work at his home-based computer business.

José's case is by no means unique. During any given year in the United States, about 15 percent of adults and about 21 percent of children are receiving some form of treatment for a psychological disorder (Druss et al., 2007; Kessler, Demler, et al., 2005; Wang, Lane, et al., 2005). The cost of treating these disorders is just one part of their economic impact—which amounts to a staggering $318 billion per year, including disability payments and lost productivity (Insel, 2008). Fortunately, the cost of treatment is more than made up for by the savings it creates. Compared with untreated patients, those who receive treatment for psychological disorders typically need fewer mental and physical health services later on (American Psychological Association, 2009; Jordan et al., 2008; Schoenbaum, Sherbourne, & Wells, 2005).

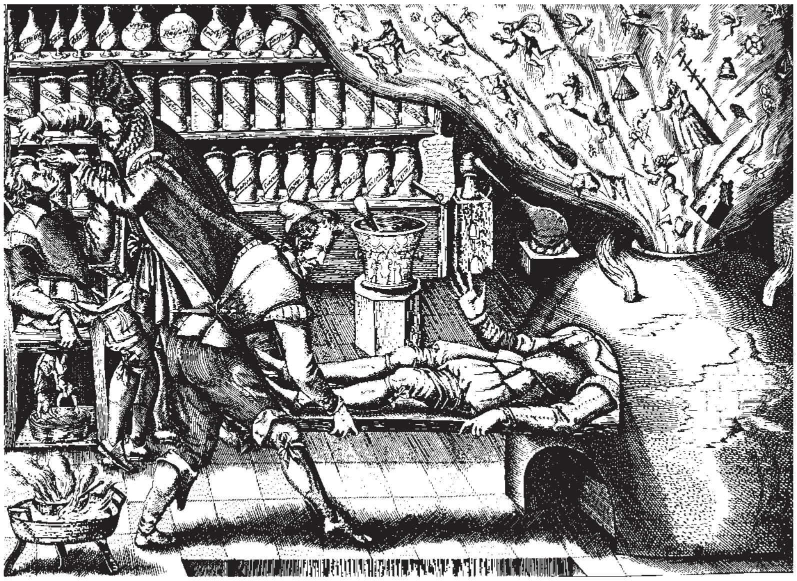
The most common targets of treatment in adults are problems involving anxiety, mood, impulse control, substance abuse, or some combination of these (Druss et al., 2007). Many people also seek treatment for problems that are not officially diagnosed as disorders, such as relationship conflicts or difficulties associated with grief, divorce, retirement, or other life transitions. Among children, the most common treatment targets are hyperactivity, oppositional behavior, anxiety, and affective disorders (Phares, 2008).

In this chapter, we describe a variety of treatment methods, most of which are based on the theories of stress and coping, personality, and psychological disorders reviewed in the chapters on those topics. First we examine the basic features common to all forms of treatment. Then we discuss approaches that rely on **psychotherapy**, the treatment of psychological disorders through psychological methods, such as talking about problems and exploring new ways of thinking and acting. These methods are based on psychodynamic, humanistic, or social-cognitive (behavioral) theories of disorder and treatment. We then consider biological approaches to treatment, which consist of prescription drugs and other physical therapies. (Many clients receive medication in addition to psychotherapy during the course of psychological treatment.)

Basic Features of Treatment

All treatments for psychological disorders share certain basic features. These common features include a *client* or patient, a *therapist* who is accepted as being capable of helping the client, and the establishment of a *special relationship* between the client and the therapist. In addition, all forms of treatment are based on some *theory* about the

psychotherapy The treatment of psychological disorders through talking and other psychological methods.



Medieval Treatment Methods

Methods used to treat psychological disorders have always been related to the presumed causes of those disorders. In medieval times, when demonic possession was widely blamed for abnormal behavior, physician-priests tried to make the victim's body an uncomfortable place for evil spirits. Here we see a depiction of demons fleeing as an afflicted person's head is placed in an oven.

causes of the client's problems (Dumont & Corsini, 2000). That theory may presume causes ranging from magic spells to infections and everything in between (Corey, 2008). The theory, in turn, leads to procedures for dealing with the client's problems. So traditional healers combat supernatural forces with ceremonies and prayers, medical doctors treat chemical imbalances with prescription drugs, and psychologists focus on altering psychological processes through psychotherapy.

People receiving treatment for psychological disorders can be inpatients or outpatients. *Inpatients* are treated in a hospital or other residential institution. They are voluntarily or involuntarily committed to these institutions because their problems are severe enough to pose a threat to their own well-being or the safety of others. Depending on their level of functioning, inpatients may stay in the hospital for a few days or weeks or, in rare cases, several years. Their treatment almost always includes psychoactive medication. *Outpatients* receive psychotherapy or prescription drugs (or both) while living in the community. Compared with inpatients, outpatients tend to have fewer and less severe symptoms of disorder and to function better in social and occupational situations (Hybels et al., 2008; Pottick et al., 2008).

Psychological treatment is provided by a diverse group of individuals (Robiner, 2006). **Psychiatrists** are medical doctors who have completed specialty training in the treatment of psychological disorders. Like other physicians, they are authorized to prescribe drugs for the relief of psychological problems. **Psychologists** who offer psychotherapy have usually completed a doctoral degree in clinical or counseling psychology, often followed by additional specialized training. Except in New Mexico and Louisiana, psychologists are not authorized to prescribe drugs, though this privilege may eventually be granted to specially trained psychologists elsewhere. Other treatment providers include *clinical social workers, marriage and family therapists,* and *licensed professional counselors,* all of whom typically hold a master's degree in their respective professions and provide therapy in a variety of settings, including hospitals, clinics, and private practice. *Psychiatric nurses, substance abuse counselors,* members of the clergy working as *pastoral counselors,* and a host of *paraprofessionals* also provide therapy services, often as part of a hospital or outpatient treatment team (Kramer, Bernstein, & Phares, 2009).

The general goal of treatment is to help troubled people change their thinking, feelings, and behavior in ways that relieve discomfort, promote happiness, and improve their overall functioning as parents, students, and workers. To reach this goal, some therapists try to help clients gain insight into the hidden causes of problems. Others seek to promote growth through more genuine self-expression, and still others help clients learn and practice new ways of thinking and acting. The particular methods

Group Therapy for War Veterans

Some psychotherapy occurs in one-to-one office sessions, but some treatment is conducted with couples, families, and groups in hospitals, community health centers, and facilities for former mental hospital residents. Therapy is also offered in prisons, at military bases, in drug and alcoholism treatment centers, and in many other places.

used in each case—some form of psychotherapy, prescription medications, or both—depend on the problems, preferences, and financial circumstances of the client; the time available for treatment; and the therapist's theoretical leanings, methodological preferences, and professional qualifications. Later, we will discuss prescription drugs and other biological treatments; here, we consider several forms of psychotherapy, each of which is based on a different theoretical perspective on mental disorder.

Although we discuss different psychotherapy methods in separate sections, keep in mind that the majority of mental health professionals see themselves as *eclectic* or *integrative* therapists: They may lean toward one set of methods, but in working with particular clients or particular problems, they incorporate other methods as well (Cook et al., 2010; Magnavita, 2006; Norcross & Goldfried, 2005).

Psychodynamic Psychotherapy

The field of formal psychotherapy began in the late 1800s when, as described in the chapter on personality, Sigmund Freud established the psychodynamic approach to understanding psychological disorders. Central to his approach, and to modern revisions of it, is the assumption that personality and behavior reflect the efforts of the ego to deal with (mostly unconscious) conflicts among various components of the personality.

Freud's method of treatment, **psychoanalysis**, was aimed at understanding these unconscious conflicts and how they affect clients. Almost all forms of psychotherapy incorporate some of his ideas, including a one-to-one treatment approach; a search for relationships between current problems and events in a client's past; an emphasis on the role of thoughts, emotions, and motivations; and a focus on the client-therapist relationship. We will describe Freud's original methods first and then consider treatments that are rooted in his psychodynamic approach.

psychoanalysis A method of psychotherapy that seeks to help clients gain insight by recognizing and understanding unconscious thoughts and emotions.

Classical Psychoanalysis

Classical psychoanalysis developed mainly out of Freud's medical practice. He was puzzled by patients who suffered from "hysterical" ailments—blindness, paralysis, or other symptoms that had no apparent physical cause (see our discussion of conversion disorders in the chapter on psychological disorders). Inspired by his colleague Josef Breuer's dramatic success in using hypnosis to treat hysterical symptoms in a patient known as "Anna O." (Freud & Breuer, 1895/2004), Freud tried similar methods with

© Geraint Lewis/Alamy

Freud's Consulting Room

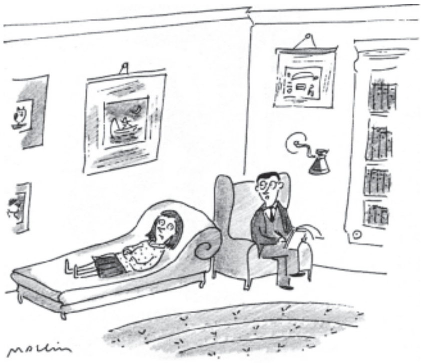
During psychoanalytic sessions, Freud's patients lay on this couch, free-associating or describing dreams and everyday events, while he sat in the chair behind them (this famous couch is now at the Freud Museum in London, which you can visit online at www.freud.org.uk). According to Freud, even apparently trivial behavior may carry messages from the unconscious. Forgetting a dream or missing a therapy appointment might reflect a client's unconscious resistance to treatment. Even accidents may be meaningful. The waiter who spills hot soup on an elderly male customer might be seen as acting out unconscious aggressive impulses against a father figure.

other hysteria patients but found them to be only partially and temporarily successful. Eventually, Freud merely asked patients to lie on a couch and report whatever thoughts, memories, or images came to mind, a process Freud called *free association.*

The results of this "talking cure" were surprising. Freud was struck by how many of his patients reported childhood memories of sexual abuse, usually by a parent or other close relative (Esterson, 2001). Freud wondered whether child abuse was rampant in Vienna, whether he was seeing a biased sample of patients, or whether his patients' memories were being distorted in some way. He eventually concluded that his patients' memories of abuse probably reflected unconscious childhood wishes and fantasies, not real events. He also believed that hysterical symptoms stem from unconscious conflicts over those wishes and fantasies.

As a result, Freud's psychoanalysis came to focus on an exploration of the unconscious and the conflicts raging within it. Classical psychoanalytic treatment aims first to help troubled people gain *insight* into their problems by recognizing unconscious thoughts and emotions. Then they are encouraged to discover, or *work through,* the many ways in which those unconscious elements continue to motivate maladaptive thinking and behavior in everyday life. The treatment may require as many as three to five sessions per week, usually over several years. Generally, the psychoanalyst is compassionate but emotionally neutral as the patient slowly develops an understanding of how past conflicts influence current problems (Gabbard, 2004).

To gain glimpses of the unconscious—and of the sexual and aggressive impulses he believed reside there—Freud looked for meaning in his patients' free associations, their dreams, their everyday behaviors, and their relationship with him. He believed that hidden beneath the obvious or *manifest content* of dreams is *latent content* that reflects the wishes, impulses, and fantasies that the dreamer's defense mechanisms keep out of consciousness during waking hours. He focused also on what have become known as "Freudian slips" of the tongue and other seemingly insignificant but potentially meaningful behaviors. So if a patient mistakenly used the name of a former girlfriend while talking about his wife, Freud might wonder if the patient unconsciously regretted his marriage. Similarly, when patients expressed dependency, hostility, or even love toward him, Freud saw it as an unconscious process in which childhood feelings and conflicts about parents and other significant people were being transferred to the therapist. Analysis of this *transference*, this "new edition" of the patient's childhood conflicts and current problems, became another important psychoanalytic method (Gabbard, 2004). Freud believed that focusing on the transference allows patients to see how old conflicts haunt their lives and helps them resolve these conflicts.



© Michael Maslin/ The New Yorker Collection/www.cartoonbank.com

"What do you think I think about what you think I think you've been thinking about?"

Analysis of the transference in this therapy relationship would be quite a challenge! This parody of psychoanalysis illustrates the point that therapists focus not only on their clients' feelings toward them but also on their feelings toward clients—called *countertransference*. For example, if transference leads a client to treat the therapist as a mother, the therapist might, because of countertransference, unintentionally begin treating the client as her child.

Contemporary Variations on Psychoanalysis

Classical psychoanalysis is still practiced, but not as much as it was several decades ago (Gabbard, 2004; Kaner & Prelinger, 2007). The decline is due to many factors, including disenchantment with Freud's personality theory, the expense of classical psychoanalysis, its limited usefulness with children, and the availability of many alternative forms of treatment, including variations on classical psychoanalysis (Roseborough, 2006; Russ, 2006; Stricker, 2006).

Some of these variations were developed by the neo-Freudian theorists discussed in the chapter on personality. As noted there, those theorists tended to place less emphasis than Freud did on the past and on unconscious impulses stemming from the id. They also tended to stress the role of social relationships in clients' problems and how the power of the ego can be harnessed to solve those problems (Gray, 2005). *Ego analysis* (Hartmann, 1958; Klein, 1960) and *individual analysis* (Adler, 1927/1999) were among the first treatments to be based on neo-Freudian theories. Some were designed for treating children (Freud, 1946; Klein, 1960). More recent variations on psychoanalysis alter the format of treatment so that it is less intense, less expensive, and more appropriate for a broader range of clients (Messer & Kaplan, 2004). Some of these variants have come to be known as *short-term psychodynamic therapy* because they aim to provide benefits in far less time than is required in classical psychoanalysis (Levenson, 2003; Rawson, 2006). However, virtually all modern psychodynamic therapies still focus attention on unconscious as well as conscious aspects of mental life, on the impact of internal conflicts, and on transference analysis as key elements in treatment (Levy et al., 2006; Luborsky & Luborsky, 2006; Vanheule et al., 2006).

In one short-term psychodynamic approach known as *object relations therapy,* the powerful need for human contact and support takes center stage (Greenberg & Mitchell, 2006). Object relations therapists believe that most of the problems for which clients seek treatment ultimately stem from their relationships with others, especially their mothers or other early caregivers. (The term *object* usually refers to a person who has emotional significance for the client.) Psychotherapists who adopt an object relations perspective take a much more active role in therapy sessions than classical analysts do—particularly by directing the client's attention to evidence of certain conflicts, rather than waiting for free association or other more subtle methods to

Play Therapy

Modern versions of psychoanalytic treatment include fantasy play and other techniques that make the approach more useful with children. A child's behavior and comments while playing with puppets representing family members, for example, are seen as a form of free association that the therapist hopes will reveal important unconscious material, such as fear of abandonment (Carlson, Watts, & Maniacci, 2006).

© Michael Newman/PhotoEdit

reveal these conflicts. Object relations therapists work to develop a nurturing relationship with their clients, providing a "second chance" for them to receive the support that may have been lacking in infancy and to counteract some of the consequences of maladaptive early attachment patterns (Kahn & Rachman, 2000; Wallerstein, 2002). For example, object relations therapists take pains to show that they will not abandon their clients, as may have happened to these people in the past. *Interpersonal therapy*, too, is rooted partly in neo-Freudian theory (Sullivan, 1954), but it focuses on helping clients explore and overcome the problematic effects of interpersonal events that occur *after* early childhood—events such as the loss of a loved one, conflicts with a parent or a spouse, job loss, or social isolation (Mufson, Polack, & Moreau, 2004; Weissman, Markowitz, & Kierman, 2007).

In another version of psychodynamic treatment, the therapist looks for a "core conflict" that appears repeatedly across a variety of relationships, including the therapy relationship (Luborsky & Luborsky, 2006). In one case, for example, "Katie" reported recurring dreams about breaking glass and accidentally cutting her therapist (Vaughan, 1998). She also recalled two childhood incidents in which she broke glassware after wandering away from her mother; in one incident, her mother cut herself while cleaning up the glass. Katie's therapist suggested that these dreams and memories indicated a core conflict about wanting to be independent of her mother yet also close to her. Addressing this conflict during therapy helped Katie realize that professional success did not require her to reject or hurt the people she cared about.

With their focus on interpersonal relationships rather than instincts, their emphasis on clients' potential for self-directed problem solving, and the reassurance and emotional support they provide, contemporary variants on classical psychoanalysis have helped the psychodynamic approach retain its influence among mental health professionals (Kaner & Prelinger, 2007; Shedler, 2010; Stiles et al., 2006).

Humanistic Psychotherapy

Whereas some therapists revised Freud's ideas, others developed radical new therapies based on the humanistic approach to personality described in the personality chapter. *Humanistic psychologists,* sometimes called *phenomenologists,* see people as capable of consciously controlling their own actions and taking responsibility for their own decisions. Most humanistic therapists believe that human behavior is motivated not by sexual or aggressive impulses but rather by an innate drive toward personal growth and improvement that is guided from moment to moment by the way people perceive their world. Disordered behavior, they say, reflects a blockage of natural growth brought on by distorted perceptions or lack of awareness of feelings. Accordingly, humanistic therapy operates on the following assumptions:

1. Treatment is an encounter between equals, not a "cure" given by an expert. It is a way to help clients restart their natural growth and to feel and behave more in line with that growth.
2. Clients will improve on their own, given the right conditions. These ideal conditions promote clients' awareness, acceptance, and emotional expression. So, like psychodynamic therapy, humanistic therapy promotes insight, but it is insight into current feelings and perceptions, not into unconscious childhood conflicts.
3. Ideal conditions in therapy can best be established through a relationship in which clients feel fully accepted and supported as human beings, no matter how problematic or undesirable their behavior may be. It is the clients' experience of this relationship that brings beneficial changes. (Notice that this assumption is shared with object relations therapy and some other forms of brief psychodynamic therapy.)
4. Clients must remain responsible for choosing how they will think and behave.

Of the many humanistically oriented treatments in use today, the most influential are client-centered therapy, developed by Carl Rogers (1951), and Gestalt therapy, developed by Frederick and Laura Perls.

Client-Centered Therapy

Carl Rogers was trained in psychodynamic therapy methods during the 1930s, but he soon began to question their value. He especially disliked being a detached expert observer whose task was to "figure out" the client. Convinced that a less formal approach would be more effective for the client and more comfortable for the therapist, Rogers allowed his clients to decide what to talk about and when, without direction, judgment, or interpretation by the therapist (Raskin & Rogers, 2005). This approach, now called **client-centered therapy** or **person-centered therapy**, relies on the creation of a relationship that reflects three intertwined attitudes of the therapist: unconditional positive regard, empathy, and congruence.

Unconditional Positive Regard

The attitude Rogers called **unconditional positive regard**, also known as **acceptance**, is expressed by treating the client as a valued person, no matter what. Rogers believed that experiencing the therapist's unconditional acceptance helps clients overcome the sense that their value as a person depends on being successful, intelligent, attractive, or meeting the other *conditions of worth* described in the personality chapter. Acceptance is communicated through the therapist's willingness to listen to the client without interrupting and without making judgments or expressing opinions. The therapist doesn't have to approve of everything the client says but must accept each statement as reflecting the client's view of the world. Client-centered therapists also avoid giving advice because acceptance includes trusting clients to solve their own problems (Merry & Brodley, 2002). They don't want their advice to convey the unspoken suggestion that clients are incompetent or dependent on the therapist's help.

Empathy

Client-centered therapists also try to appreciate the client's point of view. This goes far beyond saying, "I know what you mean." It involves an effort to see the world as each client sees it and not to look at clients from the outside. In other words, client-centered therapists work at developing **empathy**, an emotional understanding of what the client might be thinking and feeling. They convey empathy by showing that they are *actively listening* to the client. Like other skillful interviewers, they make eye contact with the client, nod in recognition as the client speaks, and give other signs of careful attention. They use **active listening**, also known as **reflection**, a paraphrased summary of the client's words that emphasizes the feelings and meanings that seem to accompany them. Active listening confirms what the client has said, shows that the therapist is interested, and helps the client to perceive and focus on the thoughts and feelings being expressed. Here is an example:

> *Client:* This has been such a bad day. I've felt ready to cry any minute, and I'm not even sure what's wrong!
>
> *Therapist:* You really do feel so bad. The tears just seem to well up inside, and I wonder if it's a little scary to not even know why you feel this way.

Notice that in rephrasing the client's statements, the therapist reflected not only the obvious feelings of sadness but also the fear in the client's voice. Most clients respond to empathic reflection by elaborating on their feelings. In this example, the client went on to say, "It *is* scary, because I don't like to feel in the dark about myself. I have always prided myself on being in control." Clients do this, said Rogers, simply because the therapist expresses the desire to listen and understand without asking disruptive questions. Active listening tends to be so effective in promoting self-understanding and awareness that it is used across a wide range of therapies (Corsini & Wedding, 2010; Miller & Rollnick, 2002). Even outside the realm of therapy, people who are

client-centered therapy (person-centered therapy) A therapy that allows the client to decide what to talk about, without direction, judgment, or interpretation from the therapist.

unconditional positive regard (acceptance) A therapist attitude that conveys caring for and recognition of the client as a valued person.

empathy The therapist's attempt to appreciate and understand how the world looks from the client's point of view.

active listening (reflection) Conveying empathy on the part of the therapist by paraphrasing a client's statements and noting accompanying feelings.

A Client-Centered Therapy Group

Carl Rogers (shown here in shirtsleeves) believed that as successful treatment progresses, clients become more self-confident, more aware of their feelings, more accepting of themselves, more comfortable and genuine with other people, more reliant on self-evaluation than on the judgments of others, and more effective and relaxed.

© Michael Rougier/Time & Life Pictures/Getty Images

thought of as easy to talk to are usually "good listeners" who reflect the important messages they hear from others.

Congruence Rogerian therapists also try to convey **congruence** (sometimes called *genuineness*) by acting in ways that are consistent with their feelings during therapy. For example, if they are confused by what a client has said, they would say so rather than trying to pretend that they always understand everything. When the therapist's acceptance and empathy are genuine, the client is able to see that relationships can be built on openness and honesty. Ideally, this experience will help the client become more congruent in other relationships.

Here is an excerpt that illustrates the three therapist attitudes we have described (adapted from Rogers, 1951, p. 49).

Client: I cannot be the kind of person I want to be. I guess maybe I haven't the guts or the strength to kill myself, and if someone else would relieve me of the responsibility or I would be in an accident I, I . . . just don't want to live.

Therapist: At the present time, things look so bad that you can't see much point in living. [*Note the empathic reflection and the attitude of acceptance.*]

Client: Yes. I wish I'd never started this therapy. I was happy when I was living in my dream world. There I could be the kind of person I wanted to be. But now there is such a wide, wide gap between my ideal and what I am. . . . [*Notice that the client responds to reflection by giving more information.*]

Therapist: It's really a tough struggle digging into this like you are, and at times the shelter of your dream world looks more attractive and comfortable. [*Note the use of empathic reflection.*]

Client: My dream world or suicide. . . . So I don't see why I should waste your time—coming in twice a week—I'm not worth it—what do you think?

Therapist: It's up to you. . . . It isn't wasting my time. I'd be glad to see you whenever you come, but it's how you feel about it. . . . [*Note the congruence in stating an honest desire to see the client and the acceptance in trusting her capacity and responsibility for choice.*]

congruence Consistency between a therapist's feelings and the therapist's behavior toward clients.

Client: You're not going to suggest that I come in oftener? You're not alarmed and think I ought to come in every day until I get out of this?

Therapist: I believe you are able to make your own decision. I'll see you whenever you want to come. [*Note again the attitude of acceptance.*]

Client: [*With a note of awe in her voice*] I don't believe you are alarmed about—I see—I may be afraid of myself, but you aren't afraid for me. [*Here the client experiences the therapist's confidence in her; in the end, the client chose not to commit suicide.*]

Gestalt Therapy

Another form of humanistic treatment was developed by Frederick S. (Fritz) Perls and his wife, Laura. A European psychoanalyst, Perls was greatly influenced by research in *Gestalt psychology.* (As described in the chapter on perception, Gestalt psychologists emphasized the idea that people actively organize their perceptions of the world.) As a result, he believed that people create their own versions of reality and that their natural psychological growth continues only as long as they accurately perceive, remain aware of, and act on their true feelings. Growth stops and symptoms appear, said Perls, when people are not aware of all aspects of themselves (Perls, 1969; Perls, Hefferline, & Goodman, 1951).

Gestalt therapy is based on these beliefs. Like client-centered therapy, **Gestalt therapy** seeks to create conditions in which clients can become more unified, self-aware, and self-accepting—and thus ready to grow again. However, Gestalt therapists use more direct and dramatic methods than Rogerians do. Often working in group settings, Gestalt therapists prod clients to become aware of feelings and impulses that they have disowned and to discard feelings, ideas, and values that are not really their own. For example, the therapist or other group members might point out inconsistencies between what clients say and how they behave. Gestalt therapists pay particular attention to clients' gestures and other kinds of "body language" that appear to conflict with what the clients are saying (Kepner, 2001). They may also ask clients to engage in imaginary dialogues, or "conversations," with other people, with parts of their own personalities, and even with objects (Elliott, Watson, & Goldman, 2004a, 2004b). Like a shy person who can be socially outgoing only while masked at a costume party, clients often find that these dialogues help them get in touch with and express their feelings (Woldt & Toman, 2005).

Over the years, client-centered and other forms of humanistic therapy have declined in popularity (Norcross, Hedges, & Castle, 2002), but Carl Rogers's contributions to psychotherapy remain significant. In particular, his emphasis on the importance of the therapeutic relationship in bringing about change has been adopted by many other treatment approaches (Kirschenbaum & Jourdan, 2005).

© Zigy Kaluzny/Stone/Getty Images

Existential Therapy

Rogers's and Perls's methods of treatment represent two prominent examples of humanisitic therapies, but there are others. For example, Rollo May (1969), May, Angel, & Ellenberger (1958), Viktor Frankl (1963), and Irwin Yalom (1980) developed therapies based on existential philosophy, which highlights such uniquely human concerns as our freedom to choose our actions, being responsible for those actions, feeling alone in the world, trying to find meaning and purpose in our lives, and confronting the prospect of death (Yalom, 2002). *Existential therapy* is designed to help people accept and deal with these concerns head-on rather than to continue ignoring or avoiding them. Because people can feel lost, alone, and unsure of life's meaning without displaying serious behavior problems, existential therapists consider their approach as applicable to anyone, whether officially diagnosed with some form of mental disorder or not.

Behavior Therapy

Psychodynamic and humanistic approaches to therapy assume that if clients gain insight, or awareness, about underlying problems, the symptoms triggered by those problems will disappear. Behavior therapists try to help clients develop a different kind of knowledge: namely, that most psychological problems are *learned behaviors* and that they can be changed by taking action to learn new ones without first searching for hidden meanings or unconscious causes (Miltenberger, 2007; Spiegler & Guevremont, 2009).

For example, consider again José, the electronics technician whose panic attacks are described in the chapter on psychological disorders. Some of these attacks had occurred while he was scuba diving, so he began making excuses when friends invited him to go diving. Avoiding diving trips eased his anxiety temporarily but did nothing to solve the problem of panic attacks. Could José solve this problem without

Gestalt therapy An active treatment designed to help clients get in touch with genuine feelings and disown foreign ones.

first discovering its "underlying meaning"? *Behavior therapy* would offer just such an alternative by first identifying the signals, rewards and punishments, and other learning-based factors that maintain José's anxiety and then helping him develop new responses in feared situations.

These goals are based on both the *behavioral approach* to psychology in general and on the *social-cognitive approach* to personality and disorder in particular. As described in the chapters on introducing psychology, on personality, and on psychological disorders, these approaches emphasize the role of learning in the development of personality, as well as in most psychological disorders. Accordingly, behaviorists tend to see those disorders as examples of the maladaptive thoughts and actions that a client has learned. For instance, behavior therapists believe that fear of leaving home (*agoraphobia*) develops through classically conditioned associations between being away from home and having panic attacks. The problem is maintained in part through operant conditioning: Staying home and making excuses for doing so are rewarded by reduced anxiety. Therapists adopting a behavioral approach argue that if past learning experiences can create problems, then new learning experiences can help eliminate those problems. So even if the experiences that led to today's problems began in the client's childhood, behavior therapy seeks to solve those problems by creating beneficial new experiences using the principles discussed in the chapter on learning.

The notion of applying learning principles in order to change troublesome behavior has its roots in the work of John B. Watson, Ivan Pavlov, and others who studied the learned nature of fear in the 1920s and 1930s. It stems, too, from B. F. Skinner's research on the impact of reward and punishment on behavior. In the late 1950s and early 1960s, researchers began to use classical conditioning, operant conditioning, and observational learning techniques in a systematic way to treat fears, improve the behavior of disruptive schoolchildren and mental patients, and deal with many other problems (Plaud, 2003; Ullmann & Krasner, 1965). By 1970, behavioral treatment had become a popular alternative to psychodynamic and humanistic methods (Martin & Pear, 2006).

The most notable features of behavioral treatment include the following:

1. Development of a productive therapist-client relationship. As in other therapies, this relationship enhances clients' confidence that change is possible and makes it easier for them to speak openly and to cooperate in treatment (Creed & Kendall, 2005; Lejuez et al., 2005).
2. A careful listing of the behaviors and thoughts to be changed (Umbreit et al., 2006). This assessment—and the establishment of specific treatment goals—often replaces the formal diagnosis used in some other therapy approaches. So instead of treating "depression" or "obsessive-compulsive disorder," behavior therapists work to change the specific thoughts, behaviors, and emotional reactions that are associated with these diagnostic labels.
3. A therapist who acts as a teacher or mentor by providing learning-based treatments, giving "homework" assignments, and helping the client make specific plans for dealing with problems rather than just talking about them (Kazantzis et al, 2005).
4. Continuous monitoring and evaluation of treatment, along with constant adjustments to any procedures that are not working as expected (Farmer & Nelson-Gray, 2005).

Because ineffective procedures are soon altered or abandoned, behavioral treatment tends to be one of the briefest forms of therapy (e.g., Flatt & King, 2008).

Behavioral treatment can take many forms. By tradition, those that rely mainly on classical conditioning principles are usually referred to as **behavior therapy**. Those that focus on operant conditioning methods are usually called **behavior modification**. And behavioral treatment that focuses on changing thoughts as well as overt behaviors is called **cognitive behavior therapy**. These methods, especially cognitive behavior therapy, are among the most important and influential approaches to psychological treatment available today (Durlak, 2006).

behavior therapy Treatments that use classical conditioning principles to change behavior.

behavior modification Treatments that use operant conditioning methods to change behavior.

cognitive behavior therapy Learning-based treatment methods that help clients change the way they think, as well as the way they behave.

Techniques for Modifying Behavior

Among the most important behavior therapy methods are systematic desensitization therapy, modeling, positive reinforcement, extinction, aversion therapy, and punishment.

© Virtual Reality Medical Center

Virtual Desensitization

This client fears heights. She is wearing a virtual reality display that creates the visual experience of being in a glass elevator that, under the therapist's careful control, seems to rise higher and higher. After learning to tolerate these realistic images without anxiety, clients are better able to fearlessly face situations they once avoided.

systematic desensitization therapy A behavioral treatment for anxiety in which clients visualize a graduated series of anxiety-provoking stimuli while remaining relaxed.

Systematic Desensitization Therapy

Joseph Wolpe (1958) developed one of the first behavioral methods for helping clients overcome phobias and other forms of anxiety. Called **systematic desensitization therapy**, it is a method in which the client visualizes a series of anxiety-provoking stimuli while remaining calm. Wolpe believed that this process gradually weakens the learned association between anxiety and the feared object until the fear disappears.

Wolpe first helped his clients learn to relax, often using the *progressive relaxation training* procedures described in the chapter on health, stress, and coping. Then, while relaxed, the clients would be asked to imagine an item from a *desensitization hierarchy,* a sequence of increasingly fear-provoking situations (see Table 16.1). The clients would imagine one hierarchy item at a time, moving to a more difficult scene only after tolerating the previous one without distress. Wolpe found that once clients could stay calm in imagined fear situations, they were better able to deal with real fear situations later on.

Wolpe's original treatment package is not used as often as it once was (McGlynn, Smitherman, & Gothard, 2004), partly because of research indicating that desensitization therapy is especially effective if it slowly and carefully presents clients with real (rather than imagined) hierarchy items (Bouton, 2002; Choy, Fyer, & Lipsitz, 2007; Marks, 2002; Tryon, 2005). This *in vivo,* or "real life," form of desensitization therapy was once difficult to arrange or control, especially in cases involving fear of flying, heights, or highway driving, for example. However, *virtual reality graded exposure* now makes it possible for clients to "experience" extremely vivid and precisely graduated versions of feared situations without actually being exposed to them. In one early study, clients who feared heights wore a head-mounted virtual reality helmet that gave them the impression of standing on bridges of gradually increasing heights, on outdoor balconies at higher and higher floors, and in a glass elevator as it slowly rose forty-nine stories (Rothbaum et al., 1995). The same technology has been used successfully in the treatment of many other anxiety disorders, ranging from fear of spiders or air travel to social phobia and posttraumatic stress disorder (Anderson, Rothbaum, & Hodges, 2003; Glantz, Rizzo, & Graap, 2003; Maltby, Kirsch, & Mayers, 2002; North, North, & Burwick, 2008; Powers et al., 2010; Rothbaum, 2006; Wiederhold & Wiederhold, 2005).

TABLE 16.1 A Desensitization Hierarchy

Desensitization hierarchies are lists of increasingly fear-provoking situations that clients visualize while using relaxation methods to remain calm. Here are a few items from the beginning and the end of a hierarchy that was used to help a client overcome fear of flying.	1. You are reading a newspaper and notice an ad for an airline. 2. You are watching a television program that shows a group of people boarding a plane. 3. Your boss tells you that you need to take a business trip by air. 4. You are in your bedroom packing your suitcase for your trip. . . . 12. Your plane begins to move as you hear the flight attendant say, "Be sure your seat belt is securely fastened." 13. You look at the runway as the plane is readied for takeoff. 14. You look out the window as the plane rolls down the runway. 15. You look out the window as the plane leaves the ground.

Exactly why systematic desensitization therapy works is not clear. Traditionally, clinicians believed that change occurs because of basic learning processes—either through classical conditioning of a new, calmer response to the fear-provoking stimulus or through extinction, as the object or situation that had been a conditioned fear stimulus repeatedly occurs without being paired with pain or any other aversive unconditioned stimulus (Hermans et al., 2006; McNeil & Zvolensky, 2000). More recent explanations emphasize that desensitization also modifies clients' cognitive processes, including their expectation that they can deal calmly and successfully with previously feared situations (Gregor & Zvolensky, 2008).

Modeling Behavior therapists sometimes help clients develop more desirable behaviors by demonstrating those behaviors. In **modeling** treatments, the client watches the therapist or other people perform desired behaviors, thus learning skills vicariously, or secondhand (Bidwell & Rehfeldt, 2004). In fear treatment, for example, modeling can teach the client how to respond fearlessly while vicariously extinguishing conditioned fear responses. One therapist showed a 24-year-old student with a severe spider phobia how to kill spiders with a flyswatter and had her practice this skill at home with rubber spiders (MacDonald & Bernstein, 1974). The combination of live modeling with gradual practice is called *participant modeling,* and it is one of the most powerful treatments for fear (Bandura, Blanchard, & Ritter, 1969; Zinbarth & Griffith, 2008; see Figure 16.1).

Modeling is also a major part of *social skills training* and *assertiveness training,* which teach clients how to interact with people more comfortably and effectively. **Social skills training** has been used to help children get along better with peers, to help social-phobic singles make conversation on dates, and to help rebuild mental patients' ability to interact normally in social situations (Al-Kubaisy & Jassim, 2003; Dowd, 2005; Lin et al., 2008). In **assertiveness training**, the therapist helps clients learn to be more direct and expressive in social situations. So instead of sheepishly agreeing to be seated at an undesirable restaurant table, clients learn to be comfortable making "I-statements," such as "I would rather sit over there, by the window." Notice that *assertiveness* does not mean aggressiveness; instead, it involves clearly and directly expressing both positive and negative feelings and standing up for one's own rights while respecting the rights of others (Alberti & Emmons, 2008; Paterson, 2000). Assertiveness training is often conducted in groups and involves both modeling and role playing of specific situations (Spence, 2003). For example, group assertiveness training has helped wheelchair-bound adults more comfortably handle the socially awkward situations in which they sometimes find themselves (Eamon, 2008).

Positive Reinforcement Behavior therapists also use systematic **positive reinforcement** to change problematic behaviors and to teach new skills in cases ranging from childhood tantrums and juvenile delinquency to schizophrenia and substance abuse (e.g., Lussier et al., 2006; Virués-Ortega, 2010). Using operant conditioning principles, they set up *contingencies,* or rules, that specify the behaviors to be strengthened through reinforcement. In a classic study, language-impaired children with autistic disorder were given grapes, popcorn, or other items they liked in return for saying "please," "thank you," and "you're welcome" during a play session. The therapist first modeled the behavior by saying the appropriate words. The children almost immediately began to utter the phrases themselves and were reinforced for doing so. The effects of positive reinforcement generalized to other situations, and as indicated in Figure 16.2, the new skills were still evident at a follow-up session six months later (Matson et al., 1990).

When working in institutions with clients suffering severe intellectual disability or other serious disorders, behavior therapists sometimes establish **token economy programs**, systems in which desirable behaviors are positively reinforced with coin-like tokens or points that can be exchanged later for snacks, access to television, or other rewards (Kazdin, 2008; LePage et al., 2003; Matson & Boisjoli, 2009; Seegert, 2003). The goal is to shape behavior patterns that will persist outside the institution (Moore et al., 2001; Paul, 2000).

modeling Demonstrating desirable behaviors as a way of teaching them to clients.

social skills training A method for teaching clients the behaviors they need in order to interact with others more comfortably and effectively.

assertiveness training A form of social skills training that focuses on teaching clients to express themselves in ways that are clear and direct.

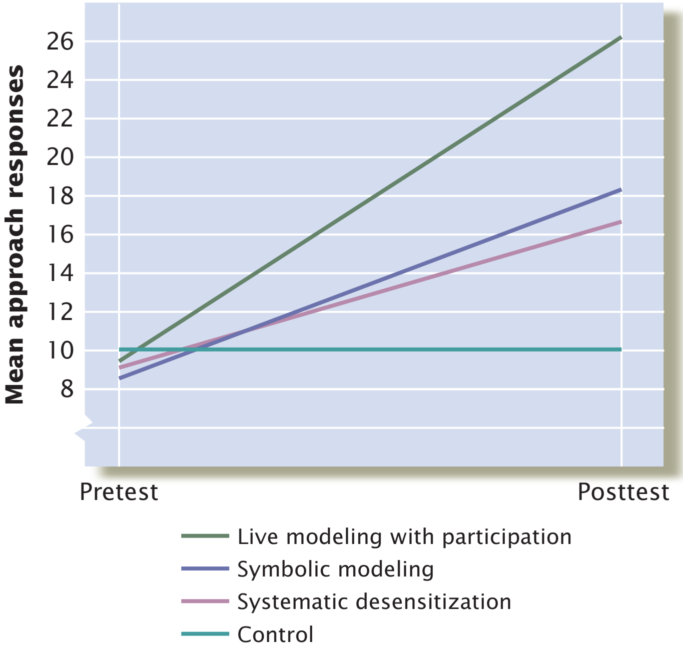
positive reinforcement A therapy method that uses rewards to strengthen desirable behaviors.

token economy programs Systems for improving the behavior of institutionalized clients in which desirable behaviors are rewarded with tokens that can be exchanged for desired items or activities.

FIGURE 16.1

Participant Modeling

In this study, participant modeling was compared with systematic desensitization, symbolic modeling (watching filmed models), and no treatment (control). Notice that compared with no treatment, all three methods helped snake-phobic clients approach live snakes, but participant modeling was clearly the best. Ninety-two percent of the participants in that group were virtually free of any fear following treatment (Bandura, Blanchard, & Ritter, 1969). The value of participant modeling has been repeatedly confirmed (e.g., Öst, Salkovskis, & Hellström, 1991; Zinbarth & Griffith, 2008).



Extinction Just as reinforcing desirable behaviors can make them more likely to occur, failing to reinforce undesirable behaviors can make them less likely to occur, a process known as **extinction**. Treatment methods that use extinction change behavior slowly but offer a valuable way of reducing inappropriate behavior in children and adolescents and in intellectually disabled or seriously disturbed adults. For example, a client who gets attention by disrupting a classroom, damaging property, or violating hospital rules might be placed in a quiet, boring "time-out" room for a few minutes to eliminate reinforcement for misbehavior (Kaminski et al., 2008; Kazdin, 2008).

FIGURE 16.2

Positive Reinforcement for a Child with Autistic Disorder

During each pretreatment baseline period, a child with autistic disorder rarely said "please," "thank you," or "you're welcome," but these statements began to occur once they were modeled and then reinforced. Did modeling and reinforcement actually cause the change? Probably, because each type of response did not start to increase until the therapist began demonstrating it.

Treating Fear Through Flooding

APPLYING PSYCHOLOGY Flooding is designed to extinguish anxiety by allowing it to occur without the harmful consequences the person dreads. These clients' fear of flying is obvious here, on takeoff, but it is likely to diminish during and after an uneventful flight. Like other behavioral treatments, flooding is based on the idea that phobias and other psychological disorders are learned and can thus be "unlearned." Some therapists prefer more gradual exposure therapies similar to those of in vivo desensitization, which start with situations that are lower on the client's fear hierarchy.

Extinction is also the basis of **flooding**, an anxiety reduction treatment in which clients are kept in a feared but harmless situation and are not permitted to use their normally rewarding escape strategies (O'Donohue, Hayes, & Fisher, 2003). The clients are flooded with fear at first, but after an extended period of exposure to the feared stimulus (a frog, say) without experiencing pain, injury, or any other dreaded result, the association between the feared stimulus and the fear response gradually weakens, and the conditioned fear response is extinguished (Basoglu, Livanou, & Salcioglu, 2003; McNally, 2007; Powers et al., 2010). In one early study, twenty clients who feared needles were exposed for two hours to the sight and feel of needles, including mild finger pricks, harmless injections, and blood samplings (Öst, Hellström, & Kåver, 1992). Afterward, all but one of these clients were able to have a blood sample drawn without experiencing significant anxiety.

Because they continuously expose clients to feared stimuli, flooding and other similar methods are also known as **exposure therapy**. Although often highly effective, these methods do cause considerable distress, much like immediately exposing a fearful client to the most difficult item on a desensitization hierarchy. Therefore, some therapists prefer more gradual exposure therapy methods, especially when treating fear that is not focused on a specific stimulus (Berry, Rosenfield, & Smits, 2009). In dealing with agoraphobia, for instance, the therapist might provide gradual exposure by escorting the client away from home for increasingly lengthy periods and eventually venturing into shopping malls and other previously avoided places (Barlow, Raffa, & Cohen, 2002; Craske et al., 2003). Clients can also practice gradual exposure methods on their own. They might be instructed, for example, to spend a little more time each day looking at photos of some feared animal or to spend some time alone in a dental chair or a dentist's waiting room. In one study, clients suffering from various phobias made as much progress after six hours of instruction in gradual self-exposure methods and daily "homework" exercises as those who received an additional nine hours of therapist-aided gradual exposure (Al-Kubaisy et al., 1992). Effective self-treatment using gradual exposure has also been reported in cases of panic disorder (Lamplugh et al., 2008), social phobia (Rapee, Gaston, & Abbott, 2009) and obsessive-compulsive disorder (Rosa-Alcazar et al., 2008).

Aversion Therapy Some unwanted behaviors—such as excessive gambling, addictive drug use, or sexual exhibitionism—become so habitual and immediately rewarding that they must be made less attractive if a client is to have any hope of giving them up. Methods for reducing the appeal of certain stimuli are known as *aversion therapy.* The name reflects the fact that these methods rely on a classical conditioning principle called **aversion conditioning** to associate nausea, painful electrical shock, or some other unpleasant stimulus with undesirable actions, thoughts, or situations (e.g., Bordnick et al., 2004).

Because aversion therapy is unpleasant and uncomfortable, because it may not work with all clients (Flor et al., 2002), and because its effects are often temporary, behavior therapists use this method relatively rarely, only when it is the best treatment choice, and only long enough to allow the client to learn more appropriate alternative behaviors.

Punishment Sometimes the only way to eliminate a dangerous or disruptive behavior is to punish it with an unpleasant but harmless stimulus, such as a shouted "No!" or a mild electrical shock. Unlike aversion conditioning, in which the unpleasant stimulus occurs along with the behavior that is to be eliminated (a classical conditioning approach), **punishment** is an operant conditioning technique; it presents the unpleasant stimulus *after* the undesirable response occurs.

The use of punishment can be appropriate and beneficial in working with certain institutionalized clients, impaired outpatients, and some children, but before using it, behavior therapists must consider several ethical and legal questions: Would the client's life be in danger without treatment? Have all other methods failed? Has an ethics

flooding An exposure technique for reducing anxiety that involves keeping a person in a feared but harmless situation.

exposure therapy Behavior therapy methods in which clients remain in the presence of strong anxiety-provoking stimuli until the intensity of their emotional reactions decrease.

aversion conditioning A method that uses classical conditioning to create a negative response to a particular stimulus.

punishment A method that uses operant conditioning to weaken undesirable behavior by following it with an unpleasant stimulus.

committee reviewed and approved the procedures? And has the client or a close relative formally agreed to the treatment? (Kazdin, 2008). When the answer to these questions is yes, punishment can be an effective and sometimes lifesaving treatment, as in the case illustrated in Figure 6.11 in the chapter on learning. But as with extinction and aversion conditioning, punishment works best when it is used only long enough to eliminate undesirable behavior and is combined with other behavioral methods designed to reinforce more appropriate behavior (Hanley et al., 2005).

Cognitive Behavior Therapy

Like psychodynamic and humanistic therapists, behavior therapists recognize that depression, anxiety, and many other behavior disorders can stem from how clients think about themselves and the world. And like other therapists, behavior therapists also try to change their clients' troublesome ways of thinking, not just their overt behavior. Unlike other therapists, however, behavior therapists rely on learning principles to help clients change the way they think. These therapists are known as *cognitive behavior therapists,* and their methods are known collectively as *cognitive behavior therapy* (Barlow, 2007; Beck, 2005; Beck, Freeman, & Davis, 2007). Suppose that a client suffers intense anxiety in social situations despite having excellent social skills. In a case such as this, social skills training would be unnecessary. Instead, the behavior therapist would use cognitive behavioral methods designed to help the client identify the recurring thoughts (such as "I shouldn't draw attention to myself") that create awkwardness and discomfort in social situations. Once these cognitive obstacles are brought to light, the therapist describes new and more adaptive ways of thinking and encourages the client to learn and practice them. As these new cognitive skills develop (e.g., "I have as much right to give my opinion as anyone else"), it becomes easier and more rewarding for clients to let these new thoughts guide their behavior (Beck, 2005).

Albert Ellis

Rational-emotive behavior therapy (REBT) focuses on altering the self-defeating thoughts that Ellis believed underlie people's behavior disorders. Ellis argued, for example, that students do not get upset because they fail a test but because they have learned to believe that failure is a disaster that indicates they are worthless. Many of Ellis's ideas have been incorporated into various forms of cognitive behavior therapy, and they helped Ellis himself deal rationally with the health problems he encountered prior to his death in 2007 (Ellis, 1997).

rational-emotive behavior therapy (REBT) A treatment designed to identify and change self-defeating thoughts that lead to anxiety and other symptoms of disorder.

Rational-Emotive Behavior Therapy

One prominent form of cognitive behavior therapy is **rational-emotive behavior therapy (REBT)**. Developed by Albert Ellis (1962, 1993, 2004a, 2004b; Ellis & MacLaren, 2005), REBT is based on the notion that anxiety, guilt, depression, and other psychological problems are caused by how people think about events, not by the events themselves. Ellis's therapy aims first at identifying self-defeating beliefs, usually in the form of *shoulds* or *musts,* such as "I should be loved or approved by everyone" or "I must be perfect in order to be worthwhile." After the client learns to recognize thoughts like these and to see how they can cause problems, the therapist uses modeling, encouragement, and logic to help the client replace maladaptive thoughts with more realistic ones. The client is then given "homework" assignments to try out these new ways of thinking in everyday situations. Here is part of an REBT session with a woman who suffered from panic attacks (Masters et al., 1987). She has just said that it would be "terrible" if she had an attack in a restaurant and that people "should be able to handle themselves!"

> *Therapist:* . . . The reality is that . . . "shoulds" and "musts" are the rules that other people hand down to us, and we grow up accepting them as if they are the absolute truth, which they most assuredly aren't.
>
> *Client:* You mean it is perfectly okay to, you know, pass out in a restaurant?
>
> *Therapist:* Sure!
>
> *Client:* But . . . I know I wouldn't like it to happen.
>
> *Therapist:* I can certainly understand that. It would be unpleasant, awkward, inconvenient. But it is illogical to think that it would be terrible, or . . . that it somehow bears on your worth as a person.

Client: What do you mean?

Therapist: Well, suppose one of your friends calls you up and invites you back to that restaurant. If you start telling yourself, “I might panic and pass out and people might make fun of me and that would be terrible,” . . . you might find you are dreading going to the restaurant, and you probably won’t enjoy the meal very much.

Client: Well, that is what usually happens.

Therapist: But it doesn’t have to be that way. . . . The way you feel, your reaction . . . depends on what you choose to believe or think, or say to yourself.

Cognitive behavior therapists use many techniques related to REBT to help clients learn to think and act in more adaptive ways. Behavioral techniques aimed at replacing upsetting thoughts with alternative thinking patterns are called *cognitive restructuring* (Lazarus, 1971; Moore, Zoellner, & Bittinger, 2004). Using these techniques, clients develop calming thoughts that they can use as part of *self-instruction* during job interviews, tense discussions, and other anxiety-provoking situations. The calming thoughts might be something like “OK, you can handle this if you just focus on the task and don’t worry about being perfect.” Sometimes the methods are expanded into *stress inoculation training,* in which clients imagine being in a stressful situation and then practice newly learned cognitive skills to remain calm (Meichenbaum, 2003). In one study of stress inoculation training, first-year law students tried out their calming new thoughts during role-playing exercises that simulated stressful classroom questioning, hostile feedback, and a competitive learning atmosphere. Following training, these students showed reductions in troublesome responses to stressors as well as improved academic performance (Sheehy & Horan, 2004).

Beck’s Cognitive Therapy Behavior therapists seek a different kind of cognitive restructuring by using Aaron Beck’s **cognitive therapy** (Beck, 1976, 1995, 2005; Beck, Freeman, & Davis, 2007). Beck’s treatment approach is based on the idea that certain psychological problems—especially those involving depression and anxiety, as well as some personality disorders—can be traced to errors in logic, or what he calls *cognitive distortions* (Beck, Freeman, & Davis, 2007; Beck et al., 2008). Common cognitive distortions include *catastrophizing* (e.g., “If I fail my driver’s test the first time, I’ll never pass it, and that’ll be the end of my social life”), *all-or-none thinking* (e.g., “Everyone ignores me”), and *personalization* (e.g., “I know those people are laughing at me”). Beck points out that these learned cognitive distortions occur so quickly and automatically that the client never stops to consider that they might not be true (see Table 16.2).

cognitive therapy A treatment in which the therapist helps clients notice and change negative thoughts associated with anxiety and depression.

TABLE 16.2 Some Examples of Negative Thinking

TRY THIS Here are a few examples of the kinds of thoughts that cognitive behavior therapists believe underlie anxiety, depression, and other behavior problems. After reading this list, try writing an alternative thought that clients could use to replace each of these ingrained cognitive habits. Then jot down a “homework assignment” that you would recommend to help clients challenge each maladaptive statement and thus develop new ways of thinking about themselves.	“I shouldn’t draw attention to myself.”
	“I will never be any good at this.”
	“It will be so awful if I don’t know the answer.”
	“Everyone is smarter than I am.”
	“Nobody likes me.”
	“I should be able to do this job perfectly.”
	“What if I panic?”
	“I’ll never be happy.”
	“I should have accomplished more by this point in my life.”

Cognitive therapy is an active, structured, problem-solving approach in which the therapist first helps clients identify the errors in logic, false beliefs, and other cognitive distortions that precede anxiety, depression, conduct problems, eating disorders, and other psychological difficulties (Beck & Rector, 2005; Drinkwater & Stewart, 2002; Fairburn, 2008; Hendricks & Thompson, 2005; Pardini & Lochman, 2003). Then, much as in the five-step critical thinking system illustrated throughout this book, those thoughts and beliefs are treated as hypotheses to be scientifically tested rather than as assertions to be accepted uncritically (Hatcher, Brown, & Gariglietti, 2001). Accordingly, therapist and client take the role of "investigators" who develop ways to test beliefs such as "I'm no good around the house." They might decide on tasks that the client will attempt as "homework"—such as cleaning out the basement, cooking a meal, paying bills, or cutting the grass. Success at accomplishing even one of these tasks provides concrete evidence to challenge a false belief that has supported depression, thus helping reduce it. As therapy progresses, clients become more skilled at recognizing and then correcting the cognitive distortions related to their problems.

As described in the chapter on psychological disorders, however, the cognitive roots of depression, anxiety, and some other disorders may involve more than specific thoughts and beliefs about certain situations. Sometimes these disorders stem from a more general cognitive style that leads people to expect that the worst will always happen to them and to assume that negative events confirm that they are completely and permanently incompetent, worthless, or unlovable (Beck & Alford, 2009). So cognitive behavior therapists also work with clients to develop more optimistic ways of thinking and to reduce their tendency to blame themselves for negative outcomes (Persons, Davidson, & Tompkins, 2001). In some cases, cognitive restructuring is combined with social skills training, practice at using logical thinking, and anxiety management techniques, all of which are designed to help clients experience success and develop confidence in situations in which they had previously expected to fail (Bryant et al., 2008).

Some cognitive therapists have also encouraged clients to use traditional Eastern practices such as meditation (see the chapter on consciousness) to help monitor problematic thoughts. This combined approach is called *mindfulness-based cognitive therapy* (Hofmann et al., 2010; Ma & Teasdale, 2004). Research in the field of positive psychology suggests, too, that the effects of cognitive behavior therapy may be enhanced through exercises deigned to promote positive emotions—such as identifying and using personal strengths and making a list of things that have gone well each day (Seligman, Berkowitz, et al., 2005; Seligman, Rashid, & Parks, 2006).

Group, Family, and Couples Therapy

The psychodynamic, humanistic, and behavioral treatments we have described are often conducted with individuals, but these treatments can also be adapted for use with groups of clients or with family units (Petrocelli, 2002; Thorngren & Kleist, 2002).

Group Therapy

Group therapy refers to the treatment of several unrelated clients under the guidance of a therapist who encourages helpful interactions among group members. Many groups are organized around a particular problem (such as alcoholism) or a particular type of client (such as adolescents). In most cases, six to twelve clients meet with their therapist at least once a week for about two hours. All group members agree to hold confidential everything that occurs during these sessions.

group therapy Psychotherapy involving several unrelated clients.

Group therapy offers several features not found in individual treatment (Marmarosh, Holtz, & Schottenbauer, 2005; Yalom, 2005). First, group therapy allows the therapist to see clients interacting with one another, which can be helpful in identifying problems in clients' interpersonal styles. Second, clients discover that they are not alone as they listen to others and realize that many people struggle with difficulties similar to theirs. This realization tends to raise each client's expectations for improvement, a factor important in all forms of treatment. Third, group members can boost one another's self-confidence and self-acceptance as they come to trust and value one another. Fourth, clients learn from one another by sharing ideas for solving problems and giving one another honest feedback about how each member "comes across" to others. Fifth, perhaps through mutual modeling, the group experience makes clients more willing to share their feelings and more sensitive to other people's needs and messages. Finally, group therapy allows clients to try out new skills—such as assertiveness—in a safe and supportive environment. So although the procedures and techniques employed in group psychotherapy may reflect any one (or more than one) of the theoretical orientations we have described in relation to individual therapy (Bieling, McCabe, & Antony, 2006), the impact of the treatment is thought to be enhanced by the nature and strength of the group itself.

Some of the advantages of group therapy are also applied in *self-help organizations.* Self-help groups, such as Alcoholics Anonymous (AA), are made up of people who share a problematic experience and meet to help one another. There are self-help groups for a wide range of problems, including alcohol and drug addiction, childhood sexual abuse, cancer, overeating, overspending, bereavement, compulsive gambling,

A Circle of Friends

This meeting of Overeaters Anonymous is but one example of the self-help movement in North America, a growing network of inexpensive mental health and antiaddiction services offered by volunteer helpers, including friends and relatives of troubled people. Millions of other people worldwide also seek help with their problems through self-help groups that meet face to face or on the Internet (Harwood & L'Abate, 2010). Newspapers typically list dozens of local self-help groups offering help with problems ranging from alcohol abuse to weight control. The services provided by these nonprofessional groups make up about 20 percent of the total mental health and antiaddiction services offered in the United States (Borkman, 1997; Regier et al., 1993; Swindle et al., 2000).

and schizophrenia (Humphreys, 2004; Kurtz, 2004). These self-help organizations operate through hundreds of thousands of local chapters, enrolling ten to fifteen million participants in the United States and about half a million in Canada (Harwood & L'Abate, 2010; Norcross et al., 2000). Many other participants in self-help groups meet solely on the Internet (Andersson, Calrbring, & Grimlund, 2008; Tan, 2008; Tillfors et al., 2008).

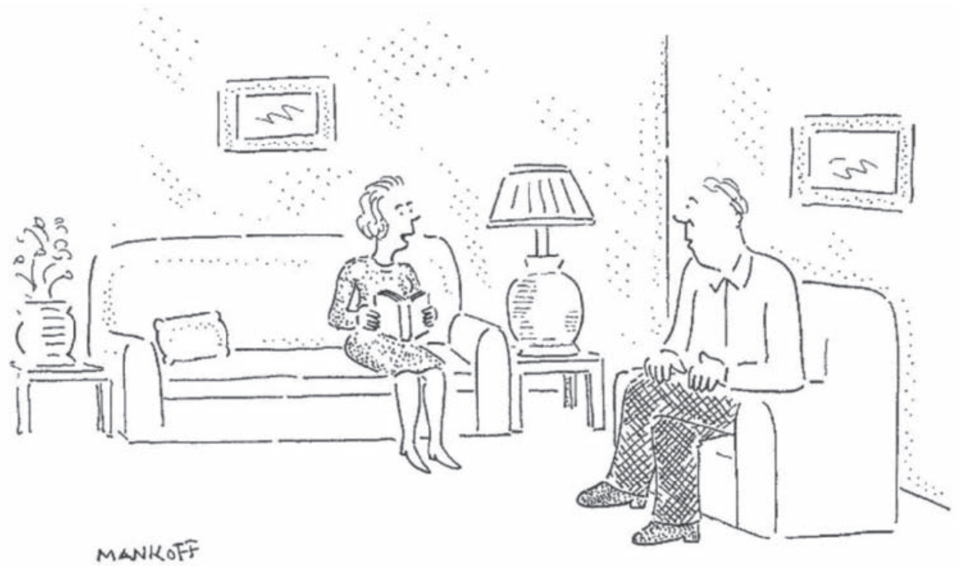
Lack of reliable data makes it difficult to assess the value of many self-help groups, but available information suggests that active members may experience moderate improvement in their lives (Carlbring & Smit, 2008; Kaskutas, Bond, & Avalos, 2009; Kelly, 2003; Mains & Scogin, 2003; Masudomi et al., 2004). Some professional therapists view these groups with suspicion; others encourage clients to participate in them as part of their treatment or as a first step toward more formal treatment (Haaga, 2000; Norcross, 2006), especially in cases of eating disorders, alcoholism, and other substance-related problems (Guimon, 2004; Scheidinger, 2004).

Family and Couples Therapy

As its name implies, **family therapy** involves treatment of two or more individuals from the same family system, one of whom—often a troubled child or adolescent—is the initially identified client. The term *family system* highlights the idea that the problems displayed by one family member usually reflect problems in the functioning of the entire family (Cox & Paley, 2003; Nichols, 2007; Williams, 2005).

Whether family therapy is based on psychodynamic, humanistic, or cognitive behavioral approaches, the family itself becomes the client, and treatment involves as many members as possible (Novick & Novick, 2005). In fact, the goal of family therapy is not just to ease the identified client's problems but also to create greater harmony and balance within the family by helping each member understand the family's interaction patterns (Blow & Timm, 2002). As with group therapy, the family format gives the therapist a chance to see how the initially identified client interacts with others, thus providing a basis for discussing topics that are important in the operation of the family system.

Fortunately, most couples are not this far out of touch, but couples therapy aims to identify the communication problems that do exist in the relationship and to help the partners speak to each other more directly and listen to each other more carefully.



"I'am sorry, dear. I wasn't listening. Could you repeat what you've said since we've been married?"

© Robert Mankoff/The New Yorker Collection/www.cartoonbank.com

family therapy Treatment of two or more individuals from the same family.

Family therapists who emphasize psychodynamic theory point out that if the parents in a family have not worked out conflicts with their own parents, these conflicts will surface in relation to their spouse and children (Scharff & Scharff, 2003). Accordingly, these family therapy sessions might focus on the parents' problems with their own parents and, when possible, include members of the older generation. A related approach, called *structural family therapy,* concentrates on family communication patterns. It focuses on changing the rigid patterns and rituals that create *alliances* (such as mother and child against father), because these alliances maintain conflicts and prevent healthy communication within the family. Structural family therapists argue that when dysfunctional communication patterns are eliminated, problematic interactions will decrease because family members no longer need them in order to survive in the family system (McLendon, McLendon, & Petr, 2005).

Behavior therapists often use family therapy sessions as meetings at which family members can discuss and agree on behavioral "contracts" (e.g., Hayes et al., 2000). Based on operant conditioning principles, these contracts establish rules and reinforcement contingencies that help parents encourage their children's desirable behaviors (while discouraging undesirable ones) and help spouses become more supportive of each other (McHale & Sullivan, 2008).

Therapists of many theoretical persuasions also offer **couples therapy**, in which communication between partners is the main focus of treatment (Christensen et al., 2010; Gurman, 2008). Discussions in couples therapy sessions are usually aimed at identifying the miscommunication or lack of communication that interferes with a couple's happiness and intimacy. In behavioral marital therapy, for example, couples learn to abide by certain "rules for talking," such as those listed in Table 16.3. Another version of couples therapy focuses on strengthening the bond between partners by teaching them how to deal with their unsolvable problems and recover from their fights by expressing at least five times as many positive statements as negative ones (Gottman, Driver, & Tabares, 2002). Some therapists help couples become closer by encouraging them to express their emotions more honestly and be more accepting of one another (Shadish & Baldwin, 2005; Wood et al., 2005).

Some therapists even offer programs designed to *prevent* marital problems in couples whose interactions suggest that they are at high risk for developing discord (Gottman, Gottman, & Declaire, 2006; Jacobson et al., 2000; Laurenceau et al., 2004). "In Review: Approaches to Psychological Treatment" summarizes key features of the main approaches to treatment that we have discussed so far.

couples therapy A form of therapy focusing on improving communication between partners.

TABLE 16.3 Some "Rules for Talking" in Couples Therapy

TRY THIS Many forms of couples therapy help partners improve communication by establishing rules such as these. Think about your own experience in relationships or your observations of couples as they interact, and then write down some rules you would add to this list. Why do you think it would be important for couples to follow the rules on your list?

1. Always begin with something positive when stating a problem.
2. Use specific behaviors rather than derogatory labels or overgeneralizations to describe what is bothersome about the other person.
3. Make connections between those specific behaviors and feelings that arise in response to them (e.g., "It makes me sad when you . . .").
4. Admit your own role in the development of the problem.
5. Be brief; don't lecture or harangue.
6. Maintain a focus on the present or the future; don't review all previous examples of the problem or ask "why" questions, such as "Why do you always . . . ?"
7. Talk about observable events; don't make inferences about them (e.g., say, "I get angry when you interrupt me" rather than "Stop trying to make me feel stupid").
8. Paraphrase what your partner has said, and check out your own perceptions of what was said before responding. (Note that this suggestion is based on the same principle as Rogers's empathic listening.)

IN REVIEW Approaches to Psychological Treatment

Dimension	Classical Psychoanalytic	Contemporary Psychodynamic	Humanistic	Behavioral/Cognitive Behavioral
Nature of the human being	Driven by sexual and aggressive urges	Driven by the need for human relationships	Has free will, choice, and capacity for self-actualization	Is a product of social learning and conditioning; behaves on the basis of past experience
Therapist's role	Neutral; helps client explore meaning of free associations and other material from the unconscious	Active; develops relationship with client as a model for other relationships	Facilitates client's growth; some therapists are active, some are nondirective	Teacher or mentor who helps client replace undesirable thoughts and behaviors; active, action-oriented
Focus	Emphasizes unresolved unconscious conflicts from the distant past	Understanding the past, but focusing on current relationships	Here and now; focus on immediate experience	Current behavior and thoughts; may not need to know original causes to create change
Goals	Psychosexual maturity through insight; strengthening of ego functions	Correction of effects of failures of early attachment; development of satisfying intimate relationships	Expanded awareness; fulfillment of potential; self-acceptance	Changes in thinking and behaving in particular classes of situations; better self-management
Typical methods	Free association; dream analysis; analysis of transference	Analysis of interpersonal relationships, including the client-therapist relationship	Reflection-oriented interviews designed to convey unconditional positive regard, empathy, and congruence; exercises to promote self-awareness	Systematic desensitization, social skills training, positive reinforcement, extinction, aversion therapy, punishment, and cognitive restructuring

1. **Object relations therapy and interpersonal therapy are both contemporary examples of the ____________ approach to psychological treatment.**
2. **Imagining increasingly fear-provoking stimuli is a treatment method called ____________.**
3. **Reflection is an interviewing technique associated mainly with the ____________ approach to treatment.**

Evaluating Psychotherapy

A national survey conducted some years ago suggested that most psychotherapists and their clients believe that psychotherapy is effective ("Mental Health," 1995; Seligman, 1996), but confirming this belief with experimental research has proved to be challenging and controversial (Beutler, 2002; Dawes, 1994; Laurenceau, Hayes, & Feldman, 2007; McHugh & Barlow, 2010; Norcross, Beutler, & Levant, 2005; Weisz, Weersing, & Henggeler, 2005; Westen, Novotny, & Thompson-Brenner, 2004).

LINKAGES Does psychotherapy work? (a link to Introducing Psychology, p. 12)

The value of psychotherapy was first widely questioned in 1952 when the British psychologist Hans Eysenck reviewed studies in which thousands of clients had received traditional psychodynamic therapy, various other therapies, or no treatment. To the surprise and dismay of many therapists, Eysenck (1952) concluded that the percentage of clients who improved following any kind of psychotherapy was actually lower than that of people who received no treatment.

Critics argued that Eysenck was wrong. They claimed that he had ignored studies that supported the value of psychotherapy and had misinterpreted the data (Bergin, 1971; de Charms, Levy, & Wertheimer, 1954; Luborsky, 1972). They pointed out, for example, that untreated clients might have been less disturbed than those in treatment. Further, they said, untreated clients might have received informal treatment from their medical doctors. Finally, the physicians who judged untreated clients' progress might have used less demanding criteria than the psychotherapists who rated their own clients. In fact, when some of these critics conducted their own counts of successes and failures, they concluded that psychotherapy tends to be more helpful than no treatment (Bergin, 1971).

Debate over Eysenck's findings—and the contradictory reports that followed them—highlighted several factors that make it so hard to answer the apparently simple question: Does psychotherapy work? For one thing, there is the problem of how to measure improvement in psychotherapy. Should it be measured with psychological tests, behavioral observations, interviews, or a combination of all three? And what kinds of tests should be used? Where should clients be observed, and by whom? Should equal weight be given to interviews with clients, friends, relatives, therapists, and teachers? The fact that these various measures don't always tell the same story about improvement makes it that much more difficult for researchers to compare or combine the results of different studies and draw conclusions about the overall effectiveness of treatment (Cuijpers et al., 2010; De Los Reyes & Kazdin, 2006; Krause, 2005; Sass, Twohig, & Davies, 2004).

The question of effectiveness is further complicated by the broad range of clients, therapists, and treatments involved in psychotherapy. Clients differ not only in terms of the problems they have but also in terms of their motivation to solve them and in the amount of stress and social support present in their environments. Therapists differ, too, not only in skill, experience, and personality but also in which of the hundreds of available treatment procedures they might select (Norcross, Beutler, & Levant, 2005; Wampold, 2005) and how long treatment lasts (Barkham et al., 2006). Further, differences in the nature and quality of the client-therapist relationship from one case to another can significantly alter the course of treatment, the clients' faith in the procedures, and their willingness to cooperate (Lambert & Barley, 2001; Zuroff & Blatt, 2006). Because clients' responses to psychotherapy can be influenced by all these factors, results from any particular treatment evaluation study may not tell us much about how well different therapists, using different methods, would do with other kinds of clients and problems (Kazdin, 2002; Roth & Fonagy, 2005). Consider the example of a classic study in which "kindly college professors" were found to be as effective as experienced psychotherapists in helping people solve their problems (Strupp & Hadley, 1979). This result would appear relevant to the question of psychotherapy's effectiveness, but a careful reading of the study shows that the clients were college students with minor problems, not severe psychological disorders. Further, the fact that these students already had a relationship with their professors may have given the professors an edge over unfamiliar therapists (Chambless & Hollon, 1998). So the outcome of this study probably does not apply to the outcomes of professional psychotherapy in general.

In short, the question of whether psychotherapy "works" is difficult or impossible to answer scientifically in a way that applies to all therapies for all disorders. However, the findings of several research reviews (Galatzer-Levy et al., 2000; Kazdin & Weisz, 2003; Leichsenring, Rabung, & Leibing, 2004; Nathan & Gorman, 2007; Shadish et al., 2000; Smith, Glass, & Miller, 1980; Weisz & Jensen, 1999) have reinforced therapists' beliefs that psychotherapy does work (see Figure 16.3).

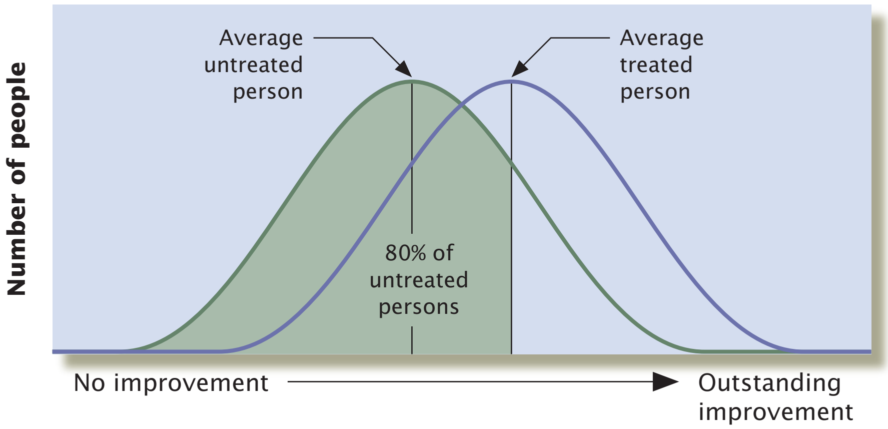


FIGURE 16.3
An Analysis of Psychotherapy Effects
These curves show the results of one large-scale analysis of the effects of psychotherapy. Notice that on average, people who received therapy for their problems were better off than 80 percent of troubled people who did not. The overall effectiveness of psychotherapy has also been confirmed in a more recent analysis of ninety treatment outcome studies (Shadish et al., 2000).

THINKING CRITICALLY

LINKAGES Can therapy change personality? (a link to Personality, p. 585)

Are All Forms of Therapy Equally Effective?

Not surprisingly, most therapists agree that all forms of therapy are effective, but most believe that the particular theoretical approach and treatment methods they use are superior to those of other therapists (Mandelid, 2003).

What am I being asked to believe or accept?

These therapists can't all be right, of course, and some researchers claim that all of them are wrong. Those researchers argue that the success of psychotherapy doesn't have much to do with theories about the causes of psychopathology or even with the specific methods that are used in treatment. All approaches, they say, are equally effective. This has been called the "Dodo Bird verdict," after the *Alice in Wonderland* character who, when called on to judge a race, answered, "Everybody has won, and all must have prizes!" (Duncan, 2002; Luborsky, Singer, & Luborsky, 1975).

What evidence is available to support the assertion?

Some evidence does indeed suggest that there are no significant differences in the overall effectiveness of psychodynamic, humanistic, and behavioral therapies. *Meta-analysis,* a statistical method that combines the results of a large number of therapy studies, has regularly shown that the three treatment approaches are associated with about the same degree of success overall (Luborsky et al., 2002; Luborsky, Rosenthal, & Diguer, 2003; Shadish et al., 2000; Shedler, 2010; Weisz, McCarty, & Valeri, 2006).

Are there alternative ways of interpreting the evidence?

It is possible, however, that evidence for the Dodo Bird verdict is based on statistical methods that tend to make all treatments look equally effective, even if they are not (e.g., Ehlers et al., 2010). For example, a meta-analysis that averages the results of many studies might miss important differences in the impact of particular treatments for particular problems. To understand how this might happen, suppose that Therapy A works better than Therapy B in treating anxiety but that Therapy B works better than Therapy A in cases of depression. If you combined the results of treatment studies with both kinds of clients, the average effects of each therapy would be about the same, making it appear that the two treatments are about equally effective.

Differences in the effects of specific treatment procedures might also be overshadowed by the beneficial *common factors* shared by almost all forms of therapy—such as the support of the therapist, the hope and expectancy for improvement that therapy creates, and the trust that develops between client and therapist (Greenberg, Constantino, & Bruce, 2006; Kazantzis, Lampropoulos, & Deane, 2005; Vocisano et al., 2004). Therapists whose personal characteristics can motivate clients to change may promote that change no matter what specific therapeutic methods they use (Norcross, 2002).

What additional evidence would help evaluate the alternatives?

Debate is likely to continue over the question of whether, on average, all forms of psychotherapy are equally effective. But many researchers believe that this is the wrong question to ask. In their view, it is pointless to compare the effects of psychodynamic, humanistic, and behavioral methods in general. It is more important, they say, to address what Gordon Paul called the "ultimate question" about psychotherapy: "What treatment, by whom, is most effective for this individual with that specific problem, under what set of circumstances?" (Paul, 1969, p. 44).

What conclusions are most reasonable?

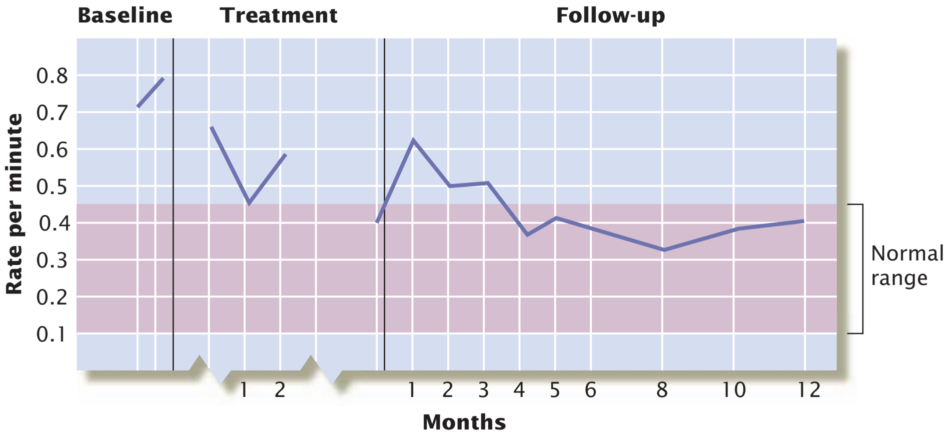
Statistical analyses show that various treatment approaches appear to be about equally effective overall. But this does not mean that every specific psychotherapy method works in the same way or that every psychotherapy experience will be equally beneficial. Clients entering therapy must realize that the success of their treatment can still be affected by the severity of their problems, the quality of the relationship they form with the therapist, and the appropriateness of the therapy methods chosen for their problems (Goldfried & Davila, 2005).

FIGURE 16.4

Clinical Significance

Evaluations of psychological treatments must consider the clinical, as well as statistical, significance of observed changes. The shaded area of this graph shows the range of deviant behaviors per minute displayed at home by normal boys. The solid line shows the average rate of deviant behaviors for boys in an operant conditioning treatment for severe behavior problems. The improvement following reinforcement of appropriate behavior was not only statistically significant (compared with the pretreatment baseline) but also clinically significant, inasmuch as the once-deviant behavior came to resemble that of normal boys.

Source: G.R. Patterson. "Intervention for Boys with Conduct Problems: Multiple Settings, Treatments, And Criteria". *Journal Of Consulting And Clinical Psychology,* vol. 42, p. 476. Copyright © 1974 by the American Psychological Association. Reprinted by permission.



Like the individuals they treat, many clinical psychologists are eager for more specific scientific evidence about the effectiveness of particular therapies for particular kinds of clients and disorders. These empirically oriented clinicians are concerned that all too often, a therapist's choice of therapy methods depends more heavily on personal preferences or current trends than on scientific evidence of effectiveness (Lynn, Lilienfeld, & Lohr, 2003; Nathan, Stuart, & Dolan, 2000; Norcross, Beutler, & Levant, 2005; Tavris, 2003). They believe that advocates of any treatment—whether it is object relations therapy or systematic desensitization—must demonstrate that its benefits are the result of the treatment itself and not just of the passage of time, the effects of repeatedly measuring progress, the client's motivation and personal characteristics, or other confounding factors. In other words, these clinicians advocate **evidence based practice**, in which practitioners base decisions about which methods to use mainly on the results of empirical evidence about the effectiveness of those methods. A movement toward evidence based practice has also appeared in the medical and dental professions (Borry, Schotsmans, & Dierickx, 2006; Niederman & Richards, 2005).

Empirically oriented psychologists also want to see evidence that the benefits of treatment are *clinically significant.* To be clinically significant, the improvement in a client's disorder following treatment must be not only measurable but also substantial enough to make treated clients' feelings and actions similar to those of people who have not experienced that disorder (Crits-Christoph et al., 2008; Kazdin, 2003; Kendall & Choudhury, 2003). For example, a reduction in treated clients' scores on an anxiety test might be *statistically significant,* but the change would not be clinically significant unless those clients now feel and act more like people without an anxiety disorder (see Figure 16.4). The need to demonstrate the clinical significance of treatment effects has become clearer than ever as increasingly cost-conscious clients—and their health insurance providers—decide whether, and how much, to pay for various psychotherapy services (Levant, 2005; Makeover, 2004; Nelson & Steele, 2006). The most scientific way to evaluate treatment effects is through experiments in which clients are randomly assigned to various treatments or control conditions and their progress is measured objectively over time.

FOCUS ON **RESEARCH METHODS**

Which Therapies Work Best for Which Problems?

To help clinicians select treatment methods on the basis of empirical evidence, the Society of Clinical Psychology (a division of the American Psychological Association) created a task force on effective psychotherapies called the Committee on Science and Practice (Sanderson, 2003).

What was the researchers' question?

The question addressed by this task force was "Which therapies have proved themselves most effective in treating various kinds of psychological disorders?"

evidence based practice The selection of treatment methods based mainly on empirical evidence of their effectiveness.

LINKAGES Is it possible to do experiments on psychotherapy? (a link to Research in Psychology, p. 42)

How did the researchers answer the question?

Working with other empirically oriented clinical psychologists, members of this task force examined the outcomes of thousands of experiments that evaluated psychotherapy methods used to treat mental disorder, marital distress, and health-related behavior problems in children, adolescents, and adults (Baucom et al., 1998; Chambless & Ollendick, 2001; Compas et al., 1998; DeRubeis & Crits-Christoph, 1998; Foley, 2004; Kazdin & Weisz, 1998; Kendall & Chambless, 1998).

What did the researchers find?

The task force found that a number of treatments—known as **empirically supported therapies**, or **ESTs**—have been validated by controlled experimental research (Chambless & Ollendick, 2001; DeRubeis & Crits-Christoph, 1998; Kendall & Chambless, 1998; Norcross, 2001, 2002). Table 16.4 contains some examples of these therapies. Notice that the treatments identified as effective for particular problems in adult clients are mainly behavioral, cognitive, and cognitive behavioral methods (Norcross, Beutler, & Levant, 2005) but that a few psychodynamic therapies (e.g., interpersonal therapy and brief dynamic therapy) also made the list (Chambless & Ollendick, 2001; Svartberg, Stiles, & Seltzer, 2004).

empirically supported therapies (ESTs) Treatments whose effects have been validated by controlled experimental research.

TABLE 16.4 Some Empirically Supported Therapies

Treatments listed as "efficacious and specific" were shown to be superior to no treatment or to some alternative treatment in at least two experiments in which clients were randomly assigned to various treatment conditions. These experiments are called *randomized clinical trials,* or *RCTs.* Also included in this category are treatments supported by scientific outcome measures from a large number of carefully conducted case studies. Treatments listed as "probably efficacious" are supported by at least one RCT or by a smaller number of rigorously evaluated case studies. Those listed as "possibly efficacious" are supported by a mixture of data, generally from single-case studies or other nonexperimental studies (Chambless & Ollendick, 2001). More information about these ESTs is available at www.psychology.sunysb.edu/eklonsky-/division12/index.html and at www.div12.org/treatments. Other reviews of empirical research are aimed at identifying potentially harmful therapies (Barlow, 2010; Lilienfeld, 2007).

Problem	Efficacious and Specific	Probably Efficacious	Possibly Efficacious
Major depression (major depressive disorder)	Behavior therapy Cognitive behavior therapy Interpersonal therapy	Brief dynamic therapy	
Specific phobia	Exposure therapy	Systematic desensitization therapy	
Agoraphobia/panic disorder	Cognitive behavior therapy	Couples training + exposure therapy	
Generalized anxiety disorder	Cognitive behavior therapy	Applied relaxation therapy	
Obsessive-compulsive disorder	Exposure therapy + response prevention	Cognitive therapy Family-assisted exposure therapy + response prevention + relaxation	Rational emotive behavior therapy + exposure therapy
Posttraumatic stress disorder		Exposure Stress inoculation Cognitive therapy + stress inoculation + exposure	Structured psychodynamic treatment
Schizophrenia	Behavioral family therapy	Family systems therapy Social skills training Supportive group therapy	Cognitive therapy (for delusions)
Alcohol abuse and dependence	Community reinforcement	Cue exposure therapy Behavioral marital therapy + disulfiram (antialcohol drug) Social skills training (with inpatients)	
Opiate abuse and dependence		Behavior therapy Brief dynamic therapy Cognitive therapy	
Marital discord	Behavioral marital therapy	Insight-oriented marital therapy

What do the results mean?

The authors of the report on ESTs, as well as supporters of their efforts, claim that by relying on analysis of experimental research, they have accomplished a scientific evaluation of various treatments. This evaluation, they say, identified a list of methods from which consumers—and clinicians who want to conduct an evidence based practice—can choose with confidence when dealing with specific disorders (e.g., Hunsley & Rumstein-McKean, 1999; Kendall & Chambless, 1998). They are even urging therapists to follow the *treatment manuals* that were used in successful research studies to help them deliver empirically supported therapies exactly as intended (Addis & Krasnow, 2000; Wade, Treat, & Stuart, 1998). The state of Kansas was the first in the United States to formally encourage the use of empirically supported treatments for children (Roberts, 2002).

Not everyone agrees with the conclusions or recommendations of the APA task force (Norcross, Beutler, & Levant, 2005; Westen & Bradley, 2005; Westen, Novotny, & Thompson-Brenner, 2004). Critics note, first, that treatment methods are not necessarily discredited just because they are not on the latest list of ESTs. Some of these treatments may not yet have been studied or validated according to the efficacy criteria selected by the task force (Lantz, 2004; Westen & Morrison, 2001). These critics also have doubts about the value of some of those criteria. They point to research showing that had the task force used different outcome criteria, it might have reached different—and perhaps less optimistic—conclusions about the value of some empirically supported treatments (Bradley, Heim, & Westen, 2005; Thompson-Brenner, Glass, & Westen, 2003). There is concern, too, about the wisdom of categorizing treatments as either "supported" or "unsupported." These simple either-or judgments seem reassuring but may fail to give a complete picture of the impact of various treatments on various clients with various problems (Krause & Lutz, 2006; Westen & Bradley, 2005).

Critics argue further that the list of ESTs is based on research that may not be relevant to clinicians working in the real world of clinical practice. They note that experimental studies of psychotherapy have focused mainly on relatively brief treatments for highly specific disorders, even though most clients' problems tend to be far more complex (Westen & Bradley, 2005). These studies focus, too, on the therapeutic procedures used rather than on the characteristics and interactions of therapists and clients (Cornelius-White, 2002; Garfield, 1998; Hilliard, Henry, & Strupp, 2000; Westen, Novotny, & Thompson-Brenner, 2004). This emphasis on procedure is a problem, critics say, because the outcome of therapy in these experiments might have been strongly affected by client-therapist factors, such as whether the random pairing of clients and therapists resulted in a match or a mismatch on certain personal characteristics. In real clinical situations, clients and therapists are not usually paired up at random (Goldfried & Davila, 2005; Hill, 2005; Hohman & Shear, 2002). Finally, because therapists participating in experimental research were required to follow standard treatment manuals, they were not free to adapt treatment methods to the needs of particular clients, as they normally would do (Garfield, 1998). Perhaps, say critics, when there is less experimental control over the treatment situation, all therapies really are about equally effective, as suggested by the statistical analyses of outcome research mentioned earlier (Shadish et al., 2000; Smith, Glass, & Miller, 1980).

In short, critics reject the EST list as a useful guide. In fact, some see it as an incomplete and ultimately misleading document (Westen & Bradley, 2005). They also worry that widespread use of treatment manuals would make psychotherapy too mechanical and less effective and would discourage therapists from developing new treatment methods (Addis & Krasnow, 2000; Beutler, 2000; Garfield, 1998).

Partly in response to these concerns, it has been suggested that the evidence in evidence based practice should come not just from randomized clinical trials but also from less rigorous studies of therapy and the therapeutic relationship and from clinicians' experiences in real-world treatment settings. This idea was formalized in an APA task force policy statement that says that "evidence based practice in psychology… is the integration of the best available research with clinical expertise in the context of patient characteristics, culture, and preferences" (American Psychological Association Presidential Task Force on Evidence Based Practice, 2006, p. 273). The contrast between this view and the one that defines effective psychotherapy in terms of ESTs illustrates the gap that remains between those who would base treatment decisions mainly on the outcome of controlled experimental research (Hunsley, 2007) and those who feel that the guidance provided by research results must be interpreted and adjusted in light of clinical judgment and experience (Zeldow, 2009).

What do we still need to know?

It remains to be seen if clinicians and researchers will be able to come together to bridge the gap between them in a way that makes the best use of both domains of knowledge in the service of clients' welfare (e.g., Barlow, 2006; Becker et al., 2009; Castonguay & Beutler, 2005; Fago, 2009). Still, the effort to identify empirically supported treatments and to develop evidence based practice in clinical psychology (Levant, 2005) represent important steps in responding to Gordon Paul's "ultimate question" about psychotherapy: "What treatment, by whom, is most effective for this individual with that specific problem, under what set of circumstances?" We still have a long way to go, but empirically oriented clinical psychologists are determined to keep moving forward. Ideally, their work will speed the development of evidence-based practice in psychology (Levant, 2005; McHugh & Barlow, 2010), in which therapists are guided by research that is clinically relevant as well as empirically supported (Arkowitz & Lilienfeld, 2006; Bray, 2010).

We have seen that the Dodo Bird verdict is probably incorrect, and it is certainly incomplete. Although different treatments can be equally effective in addressing some disorders, empirical research shows that for other disorders, certain therapies tend to be more effective than others. For example, when differences show up in comparative studies of adult psychotherapy, they reveal a small to moderate advantage for behavioral and cognitive behavioral methods, especially in the treatment of phobias and certain other anxiety disorders (Butler et al., 2006; Craske & Barlow, 2008; Eddy et al., 2004; Hollon, Stewart, & Strunk, 2006; Schnurr et al., 2007; Tolin, 2010) and in the prevention and treatment of eating disorders (Hendricks & Thompson, 2005; Stice & Shaw, 2004; Wilson et al., 2010). The same overall trend holds true in the treatment of child and adolescent clients (Carr, 2009; Kazak et al., 2010; Kendall et al., 2008; Weisz, Doss, & Hawley, 2005).

This research provides valuable guidelines for matching treatments to disorders, but it doesn't guarantee success. The outcome of any given case will also be affected by client characteristics, therapist characteristics, and the quality of the relationship that develops between them (e.g., Hill, 2005; Sherer & Schreibman, 2005). Indeed, the client-therapist relationship plays a consistent role in the success of all forms of treatment (Brown & O'Leary, 2000; Constantino et al., 2005; Horvath, 2005; Karver et al., 2006; Uwe, 2005; Zuroff & Blatt, 2006). Certain people seem to be particularly effective in forming productive human relationships. Even without formal training, these people can sometimes be as helpful as professional therapists thanks to personal qualities that are inspiring, healing, and soothing to others (Hill & Lent, 2006; Ronnestad & Ladany, 2006). Their presence in self-help groups may well underlie some of the success of those groups and, among professionals, may help account for the success of many kinds of formal therapy.

Before choosing a therapist and treatment approach, then, clients should keep Paul's "ultimate question" in mind. They should carefully consider (1) empirical research about the best treatment for their particular problem; (2) what treatment approach, methods, and goals they find most comfortable and appealing; (3) information about the therapist's "track record" of clinically significant success with a particular method for treating problems similar to those they face; and (4) the likelihood of forming a productive relationship with the therapist. This last consideration assumes special importance when client and therapist do not share similar social or cultural backgrounds.

Sociocultural Factors in Psychotherapy

Imagine that after moving to an unfamiliar country to pursue your education or career, you become severely depressed. A friend there refers you to a therapist who specializes in depression. At your first session, the therapist stares at you intently, touches your head for a moment, and says, "You have taken in a spirit from the river, and it is trying to get out. I will help." The therapist then begins chanting softly and appears to go into a trance. What would you think? Would you return for a second visit? If you are like most people raised in a Western culture, you probably wouldn't continue treatment because this therapist may not share your beliefs and expectations about what is wrong with you and what should be done about it.

Such sociocultural clashes occur whenever clients come to therapy with a cultural or subcultural worldview that is not shared by their therapist (Seeley, 2006). Suppose, for example, that a therapist suggests that a client's panic attacks are a reaction to stress but the client is sure that the attacks are punishment for having offended a dead ancestor. That client may not easily accept a treatment based on the principles of stress management. Similarly, a therapist who believes that people should confront and overcome life's problems might run into trouble when treating clients whose cultural or religious training encourages calm acceptance of these problems (Sue et al., 2009). In such cases, the result may be much like two people singing a duet using the same music but different lyrics (Martinez et al., 2005).

In the United States, sociocultural clashes may be partly to blame for the underuse of or withdrawal from mental health services by recent immigrants, as well as by African Americans, Asian Americans, Hispanic Americans, American Indians, and members of other minority populations (Duran et al., 2005; Gone, 2004; Neighbors et al., 2007; Sanders-Thompson, Bazile, & Akbar, 2004; Thurston& Phares, 2008; Wang, Lane, et al., 2005). In other words, sociocultural differences between clients and therapists—in religious faith, gender, age, ethnicity, sexual orientation, socioeconomic background, and the like—can sometimes be a source of miscommunication or mistrust (Seeley, 2006), potentially impairing both their working relationship and the client's motivation to change (Jones, Botsko, & Gorman, 2003; Wintersteen, Mensinger, & Diamond, 2005; Vasquez, 2007). Accordingly, major efforts are under way to ensure that cultural differences between clients and therapists do not interfere with the delivery of treatment to anyone who wants or needs it. Virtually every mental health training program in North America is seeking to recruit more students from traditionally underserved minority groups so as to eventually make it easier to match clients with therapists from similar cultural backgrounds (e.g., Kersting, 2004; Meredith & Baker, 2007; Rogers & Molina, 2006).

In the meantime, many minority clients are likely to encounter a therapist from a differing background, so researchers have also examined the value of matching therapeutic techniques with clients' culturally based expectations and preferences (Jones, Botsko, & Gorman, 2003; Li & Kim, 2004; Muñoz & Mendelson, 2005). For example, many clients from collectivist cultures—in which the emphasis is on meeting the expectations of family and friends rather than satisfying personal desires—might expect to receive instructions from a therapist about how to overcome problems. How would such clients respond to a therapist whose client-centered treatment emphasizes more individualist goals, such as being independent and taking responsibility for the direction of change? David Sue and his students investigated the hypothesis that the collectivist values of Asian cultures would lead Asians and Asian Americans to prefer a directive, problem-solving approach over nondirective, client-centered methods. In this classic study, Sue (1992) found that a preference for directive treatment was higher among foreign-born Asians than among American-born Asians and European Americans. Individual differences still exist, however, so two people from the same culture may react quite differently to a treatment that group research suggests should be ideal for both of them. In Sue's study, for example, more than a third of the foreign-born Asians preferred

Preparing for Therapy

Special pretreatment orientation programs may be offered to clients who, because of sociocultural factors, are unfamiliar with the rules and procedures of psychotherapy. These programs provide a preview of what psychotherapy is, how it can help, and what the client is expected to do to make it more effective (Reis & Brown, 2006; Swartz, Zuckoff, et al., 2007).

the nondirective approach, and 28 percent of the European Americans preferred the directive approach.

Today, psychotherapists are more sensitive than ever to the cultural values of particular groups and to the difficulties that can impair intercultural communication (Fields, 2010; Hays & Iwamasa, 2006; Hwang, 2006; Martinez et al., 2005; Sue et al., 2009). Some U.S. states now require clinical and counseling psychologists to complete courses or gain supervised experience focused on the role of cultural factors in therapy before being licensed (Rehm & DeMers, 2006). Similar cultural diversity training is required for all graduate students in clinical and counseling psychology training programs accredited by the American Psychological Association (Commission on Accreditation, 2009; Kersting, 2004; Smith, Constantine, et al., 2006). This special training helps clinicians and graduate students appreciate, for example, that it is considered impolite in some cultures to make eye contact with a stranger. Having that information makes it easier for them to recognize that clients from those cultures are not necessarily depressed, lacking in self-esteem, or inappropriately submissive just because they look at the floor during an interview.

There is no guarantee that cultural diversity training will improve treatment results (Shin et al., 2005), but there is some evidence that it can help (e.g., Constantine, 2002; Razali, Aminah, & Umeed, 2002; Sue et al., 2009). Although it is unrealistic to expect all therapists to be equally effective with clients of every ethnic or religious background, cultural diversity training offers a way to improve their *cultural sensitivity,* an extension of Carl Rogers's concept of empathy. When therapists appreciate the client's view of the world, it is easier for them to set goals that are in harmony with that view (Dyche & Zayas, 2001; Pedersen & Draguns, 2002; Stuart, 2004). Minimizing the chances of cultural misunderstanding and miscommunication is one of the many ethical obligations that therapists assume whenever they work with clients. Let's consider some others.

Rules and Rights in the Therapeutic Relationship

Treatment can be an intensely emotional experience. The client-therapist relationship can profoundly affect a client's life, so professional ethics require the therapist to ensure that this relationship does not harm the client. For example, the American Psychological Association's *Ethical Principles of Psychologists and Code of Conduct* forbids a sexual relationship between therapist and client—during treatment and for at least two years afterward—because of the severe harm it can cause the client (American Psychological Association [APA], 2002b; Behnke, 2004; Bersoff, 2008). Even after two years have passed, therapists may not ethically pursue a sexual relationship with a former client unless they can demonstrate that the relationship is not exploitative or otherwise harmful to that client. Laws in some U.S. states prohibit therapists from *ever* having a sexual relationship with a former client, and these laws take precedence over the APA's code of conduct.

These same ethical standards require that therapists, with a few exceptions, keep everything a client says in therapy strictly confidential. Confidentiality is one of the most important features of a successful therapeutic relationship because it allows the client to discuss unpleasant or embarrassing feelings, behaviors, or events without fear that the therapist might disclose this information to others. Professionals sometimes consult with one another about their clients, but they do not identify clients by name, and they do not reveal information to outsiders (even to members of the client's family) without the client's consent. The APA's code of ethics also includes standards relating to the growing number of clients who seek psychological services via *telehealth* or *e-health* channels, which include telephone, videoconferencing, e-mail, and other Internet links (Andersson, 2009; APA, 2002b; Barnett & Scheetz, 2003; Christensen, Griffiths, & Jorm, 2004; Mohr, Hart, et al., 2005; Ruskin et al., 2004). One of these standards, for example, requires therapists to inform clients that others might be able to gain access to their e-mail messages and that no formal client-therapist relationship exists in e-mail exchanges.

Rights of the Mentally Ill

In 1996, after years of odd behavior—including vague threats against government officials and claims that the government was spying on him through TV satellite dishes—Russell Eugene Weston Jr. was diagnosed with paranoid schizophrenia. He was hospitalized for seven weeks but had to be released when doctors determined that he was not a threat to himself or others as long as he took his prescribed medication. He failed to do so, however, and in July 1998, Weston killed two police officers during an armed rampage at the U.S. Capitol. Cases such as his are frustrating to mental health professionals, whose decisions about hospitalization must balance the rights of mental patients against those of the public.

Professional rules about confidentiality are backed up in most U.S. states by laws recognizing that information revealed in therapy—like information given to a priest, a lawyer, or a physician—is privileged communication. In 1996, a U.S. Supreme Court ruling also established psychotherapist-client privilege in the federal courts (DeBell & Jones, 1997; Knapp & VandeCreek, 1997). This means that by asserting *privilege,* a therapist can refuse, even in court, to answer questions about a client or to provide personal notes or tape recordings from therapy sessions (Kaplan, 2005). Only under special circumstances can therapists be legally required to violate confidentiality (Donner et al., 2008). These circumstances include those in which (1) a client is so severely disturbed or suicidal that hospitalization is needed, (2) a client uses his or her mental condition and history of therapy as part of his or her defense in a civil or criminal trial, (3) the therapist must defend against a client's charge of malpractice, (4) a client reveals information about sexual or physical abuse of a child under 18, and (5) the therapist believes a client may commit a violent act against a specific person.

This last condition poses a dilemma: Suppose that a client says, "Someday I'm going to kill that brother of mine!" Should the therapist consider this a serious threat and warn the brother? In most cases, there is no real danger, but there have been tragic exceptions. For example, Prosenjit Poddar, a graduate student receiving therapy at the University of California at Berkeley in 1969, revealed his intention to kill Tatiana Tarasoff, a young woman whom he had tried to date the previous year but who had rejected him. The therapist took the threat seriously, consulted his supervisor, and asked the campus police to take Poddar to a hospital. They did not do so, however, and neither Tarasoff nor her parents were warned about the possible danger (Ewing & McCann, 2006). After dropping out of therapy, the client killed Tarasoff, whose parents later sued the university, the campus police, and the therapist. They won their case, thus setting an important precedent (Yufik, 2005). Several U.S. states now have laws that make a therapist liable for failing to take steps to protect those who are threatened with violence by the therapist's clients (Bersoff, 2008; Werth, Welfel, & Benjamin, 2009). Other states allow therapists more discretion in warning or protecting potential victims (Carson & Bull, 2003).

A different set of laws protect people in the United States from being committed to mental hospitals without good cause (B. R. Johnson, 2004). Federal court decisions have given clients threatened with commitment the right to have written notice; an opportunity to prepare a defense with the help of an attorney; a court hearing, with a jury if desired; and the right to invoke the Fifth Amendment to avoid self-incrimination. Furthermore, before people can be forcibly committed, the state must provide "clear and convincing" evidence that they are not only mentally ill but also gravely disabled or an "imminent danger" to themselves or others. Most states now require a periodic review of every committed person's records to determine whether release from a mental hospital is appropriate.

While hospitalized, patients have the right to receive treatment, but they also have the right to refuse certain forms of treatment (Carson & Bull, 2003). These rules are designed to protect hospitalized mental patients from abuse, neglect, or exploitation, but they can also create difficulties and dangers. Consider Russell Eugene Weston Jr., a former mental patient who was hospitalized after being charged with the murders of two police officers in 1998. Facing a possible death penalty but judged mentally incompetent to stand trial, he asserted his right to refuse prescription drug treatment that would make him competent. After a long legal battle, Weston was forced to take medication. Prosecutors successfully argued that the right to refuse treatment does not extend to hospitalized patients who pose a danger to themselves or others (Manahan, 2004).

Hospitalized patients who do not pose such dangers—including those whose dangerous impulses are being suppressed by prescription drugs—have the right to be subjected to minimal restriction of their freedom (Bell, 2005). Accordingly, they are released from mental hospitals, usually with a supply of medication that they are to take on their own. Unfortunately, not all these patients follow doctors' orders. Like Weston, Andrew Goldstein was not considered dangerous as long as he took his antipsychotic medication, but after being released from a New York City mental hospital in December 1998, he stopped doing so. About two weeks later, Goldstein pushed Kendra Webdale to her death under the wheels of a subway train (Perlin, 2003). Cases such as these put the staff at mental health facilities in a bind—they worry about being sued if they keep patients unnecessarily confined or if someone is harmed by a patient they have released too soon. In an effort to strike a balance between the rights of mental patients and those of the public, several states now have laws requiring outpatient treatment for people who are dangerous when not medicated. The New York statute is known as Kendra's Law (Appelbaum, 2005).

Hospital Restraints

Here are examples of the chains, straitjackets, belts, and covered bathtubs that were used to restrain disruptive patients in North American and European mental hospitals in the 1800s and well into the 1900s. These devices were gentle compared with some of the methods endorsed in the late 1700s by Benjamin Rush. Known as the "father of American psychiatry," Rush advocated curing patients by frightening or disorienting them—for example, by placing them in a coffinlike box, which was then briefly immersed in water.

Biological Treatments

Prescription drugs that can ease the symptoms of psychological disorders are the latest and most effective in a long line of biological treatments based on the idea that psychological problems have physical causes. Hippocrates, a physician of ancient Greece, was among the first to propose this idea, and the treatments he prescribed included rest, special diets, laxatives, and abstinence from alcohol and sex. In the mental hospitals of Europe and North America during the sixteenth through eighteenth centuries, treatment of psychological disorders was based in part on Hippocrates' methods and consisted mainly of physical restraints, laxative purges, draining of "excess" blood, and induced vomiting. Cold baths, hunger, and other physical discomforts were also used in efforts to shock patients back to normality (Jones, 1923). Even as recently as the mid-1900s, physicians treated most forms of psychological disorder by means of brain surgery or electric shock.

Psychosurgery

Psychosurgery involves the destruction of brain tissue for the purpose of treating mental disorder. Among the first to try these procedures was a Portuguese neurosurgeon named António Egas Moniz. In 1935, he developed a technique, called *prefrontal lobotomy,* in which small holes are drilled in the forward portion of the skull and a sharp instrument is inserted and moved from side to side to cut connections between the prefrontal cortex and the rest of the brain (Freeman & Watts, 1942; Moniz, 1948). The theory was that emotional reactions in disturbed people become exaggerated due to neural processes in the frontal lobes and that the lobotomy disrupts these processes. During the 1940s and 1950s, psychosurgery became almost routine in the treatment of schizophrenia, depression, anxiety, aggressiveness, and obsessive-compulsive disorder (Valenstein, 1980). Unfortunately, brain surgery is risky and sometimes fatal, its benefits are uncertain, and its side effects and complications, including epilepsy, are irreversible (Balon, 2004; Martin et al., 2001; Rueck, Andreewitch, & Flyckt, 2003). Today, psychosurgery is performed only in rare cases in which all else has failed; guided by brain-imaging techniques, it focuses on much smaller areas of the brain than those involved in lobotomies (Anderson & Booker, 2006; Dougherty et al., 2002; Helmes & Velamoor, 2009).

Electroconvulsive Shock Therapy

In the 1930s, a Hungarian physician named Ladislaus von Meduna used a drug to induce convulsions in schizophrenics. He believed—incorrectly—that because schizophrenia and epilepsy rarely occur in the same person, epileptic-like seizures might combat schizophrenia. In 1938, two Italian physicians, Ugo Cerletti and Lucio Bini, created seizures by passing an electric current through schizophrenics' brains. During the next twenty years or so, this procedure, called **electroconvulsive shock therapy (EST)**, became a routine treatment for schizophrenia, depression, and sometimes mania. Although many patients improved, they often relapsed. The benefits of EST also had to be weighed against side effects such as memory loss, confusion, speech disorders, and occasionally death due to cardiac arrest (Lickey & Gordon, 1991; Shiwach, Reid, & Carmody, 2001). In an effort to make EST safer, doctors now administer an anesthetic to render patients unconscious before the shock is delivered, along with a muscle relaxant to prevent bone fractures during convulsions. Also, the shock now lasts only about half a second and is usually delivered to only one side of the brain (Sackeim et al., 2000). Finally, in contrast to the dozens of treatments administered decades ago, patients now receive a total of only six to twelve shocks, usually administered two days apart (Shorter & Healy, 2007).

Electroconvulsive Shock Therapy

Approximately one hundred thousand individuals receive EST each year in the United States (Payne & Prudic, 2009). Because of its dramatic and potentially dangerous nature, the use of EST remains controversial (Breggin, 2007). Critics want it outlawed, but proponents insist that the benefits of EST for certain patients outweigh its potential costs.

The use of EST has declined in the United States since the 1950s, but it is still performed on about one hundred thousand people each year (Payne & Prudic, 2009). It is administered mainly to patients suffering severe depression (and occasionally to manic patients) who do not respond to prescription drugs (de Macedo-Soares et al., 2005; Payne & Prudic, 2009; Rasmussen, 2003). EST can be effective in some of these cases—especially when followed up with medication (Sackheim et al., 2009)—and it does not appear to cause brain damage, even after repeated administrations (e.g., Anghelescu et al., 2001; Dwork et al., 2004; Kellner et al., 2005, 2006; Payne & Prudic, 2009).

No one knows for sure how and why EST works (Greenberg & Kellner, 2005; Shorter & Healy, 2007), but the fact that it helps some patients has led EST researchers to seek even safer methods of inducing seizures. Among the techniques being investigated are *magnetic seizure therapy* (*MST*), which induces seizures with timed pulses of magnetic energy (Lisanby, 2004), and a related but less intense procedure called *repetitive transcranial magnetic stimulation* (*rTMS*) (Couturier, 2005; Schutter, 2005). *Deep brain stimulation* (*DBS*) does not cause seizures but requires the placement of electrodes in the brain to provide continuous pulses of electricity to a particular target area. Some researchers suggest that these treatments may be of value in severe cases of depression and obsessive-compulsive disorder that are unresponsive to other treatments (George et al., 2010; Goodman et al., 2010; Hardesty & Sackeim, 2007; Martiny, Lunde, & Bech, 2010).

psychosurgery Surgical procedures that destroy tissue in small regions of the brain in an effort to treat psychological disorders.

electroconvulsive shock therapy (EST) Brief electrical shock administered to the brain, usually to reduce depression that does not respond to drug treatments.

Psychoactive Drugs

The decline in use of psychosurgery and EST after the 1950s came not only because of their complications and general distastefulness but also because *psychoactive drugs* had begun to emerge as more convenient and effective treatment alternatives. These drugs are now the most common biological treatment for all forms of psychological disorder. In the chapters on biological aspects of psychology and on consciousness, we discuss how psychoactive drugs affect neurotransmitter systems and consciousness. Here we describe how some of these drugs are prescribed to combat schizophrenia, depression, mania, and anxiety.

Neuroleptic Drugs

Neuroleptic drugs, or *antipsychotics,* dramatically reduce the intensity of psychotic symptoms such as hallucinations, delusions, paranoid suspiciousness, disordered thinking, and confused speech in many mental patients, especially those with schizophrenia. The most widely used antipsychotic drugs are the *phenothiazines* (pronounced "fee-noh-THY-uh-zeenz"), of which the first, *chlorpromazine* (marketed as Thorazine in the United States and as Largactil in Canada and the United Kingdom), has been especially popular. Another neuroleptic drug, *haloperidol* (sold as Haldol), is about as effective as the phenothiazines, but it causes less sedation (Julien, 2008). Patients who do not respond to one type of neuroleptic drug may respond to the other (Schatzberg, Cole, & DeBattista, 2007). Between 60 and 70 percent of the people who receive these medications show improvement, though fewer than 30 percent respond well enough to live independently (Freedman, 2003).

Neuroleptic drugs also have side effects ranging from dry mouth and dizziness to symptoms similar to those of Parkinson's disease, including muscle rigidity, restlessness, tremors, and slowed movement. Some of these side effects can be treated with medication, but at least 25 percent of patients who take chlorpromazine or haloperidol for several years develop an irreversible movement disorder called *tardive dyskinesia* (*TD*), which causes uncontrollable, repetitive actions, often including twitching of the face, flailing of the arms and legs, and thrusting of the tongue (Miller, McEvoy, et al., 2005).

Among a newer generation of antipsychotic drugs (also called *atypical neuroleptic drugs*) is *clozapine* (Clozaril), which has effects like those of the phenothiazines but is less likely to cause movement disorders (Louzá & Bassit, 2005; Rochon et al., 2005). Although no more effective overall than the phenothiazines, clozapine has helped many patients who did not respond to the phenothiazines or haloperidol (Green & Patel, 1996; Rabinowitz et al., 2001). Unfortunately, taking clozapine carries a slight risk of developing a fatal blood disease called *agranulocytosis* (Ginsberg, 2006). Weekly blood tests to detect early signs of this disease greatly increase the cost and inconvenience of using clozapine, so it is usually prescribed only for patients who have not responded well to other medications and are willing to have their blood drawn frequently.

Several other atypical neuroleptic drugs have now been introduced, including *risperidone* (Risperdal), *olanzapine* (Zyprexa), *quetiapine* (Seroquel), *ziprasidone* (Geodon), and *aripiprazole* (Abilify). These medications are expensive, but they have fewer side effects than clozapine, and they do not cause agranulocytosis (Schatzberg, Cole, & DeBattista, 2007). Like clozapine, they also appear to reduce the negative symptoms of schizophrenia, such as lack of emotion, social withdrawal, and reduced speech (e.g., Fleischhacker & Widschwendter, 2006; Kane et al., 2003; Kapur, Sridhar & Remington, 2004; Potkin et al., 2003; Wang et al., 2010). There is some doubt, though, as to whether these newest atypical neuroleptic drugs are significantly more effective than older drugs (Matza, Baker, & Revicki, 2005), partly because 60 to 80 percent of patients may stop taking them due to weight gain, nervous tics, and other bothersome side effects (Lieberman et al., 2005; Swartz, Perkins, et al., 2007).

A Natural Cure?

An herbal remedy from a plant called Saint John's wort has become a popular nonprescription treatment for depression. One of its active ingredients, hypericin, is thought to affect neurotransmitters in the brain much as Prozac or Zoloft does. One double-blind study showed Saint John's wort to be no more effective than a placebo for treating major depression (Hypericum Depression Trial Study Group, 2002), though others have shown it to be as effective as Prozac in cases of milder depression (e.g., Hammerness, Basch, & Ulbricht, 2003; Szegedi et al., 2005). Final conclusions about the safety and effectiveness of Saint John's wort must await the results of further research (National Center for Complementary and Alternative Medicine, 2008).

Antidepressant Drugs Soon after antipsychotic drugs appeared, they were joined by **antidepressant drugs**, a class of medications that now constitute the most widely prescribed treatment for depression (Schatzberg, Cole, & DeBattista, 2007; Thomson Healthcare, 2007). There are several classes of antidepressant drugs. The *monoamine oxidase inhibitors* (*MAOIs*) are used to treat many cases of depression, especially clients who also experience anxiety and panic (Julien, 2008). The *tricyclic antidepressants* (*TCAs*) are another popular class of antidepressant drugs. The TCAs have been prescribed more frequently than MAOIs because they seem to work somewhat better and have fewer side effects. However, overdoses of TCAs can be fatal, as can taking TCAs and drinking alcohol at the same time (Nutt, 2005a). Still, if side effects are controlled, tricyclics can be effective in treating depression and can also reduce the severity of panic attacks in some cases of panic disorder.

Today, the most popular medications for depression are those that affect the neurotransmitter *serotonin*. The most prominent drug in this group is *fluoxetine* (Prozac), which after its introduction in 1986 quickly became the most widely used antidepressant drug in the United States (Brambilla et al., 2005). Its popularity is due to the fact that it is as effective as older antidepressant drugs and in most cases has milder side effects—mainly weight gain, sexual dysfunction, and gastrointestinal problems (Nutt, 2005a; Patten et al., 2005). An improved version of Prozac, containing a purer active ingredient called *R-fluoxetine,* is now available (Norman & Olver, 2004). Other even newer antidepressant drugs, including *venlafaxine* (Effexor), *nefazodone* (Serzone), *bupropion* (Wellbutrin), *escitalopram* (Lexapro), *sertraline* (Zoloft), and *duloxetine* (Cymbalta), are also now on the market (Brambilla et al., 2005; Hirschfeld & Vornik, 2004; Schatzberg, Cole, & DeBattista, 2007; Zimmerman, Posternak, et al., 2005).

About 50 to 60 percent of patients who take antidepressant medication experience improved mood, greater physical activity, increased appetite, and better sleep (Hollon, Thase, & Markowitz, 2002). These benefits are seen in only 10 to 20 percent of the most severe cases of depression, however (Fournier et al., 2010), and for most patients, improvement does not appear for at least a week or two after treatment begins (Quitkin et al., 2003; Taylor, Freemantle, et al., 2006). This delayed response seems odd because antidepressants have almost immediate effects on neurotransmitters, usually increasing the availability of serotonin or norepinephrine in the brain. As discussed in the chapter on psychological disorders, these neurotransmitters are thought to be involved in the biology of depression, so perhaps the time lag reflects the operation of a long-term compensatory process in the nervous system.

Doubt has arisen about the extent to which the results of antidepressant medications are due to the chemical action of their active ingredients. An analysis of clinical trial data submitted to the U.S. Food and Drug Administration by the makers of six widely prescribed antidepressant drugs showed that in 57 percent of the trials, antidepressant drugs did only a little better at relieving depression than placebos ("sugar pills") (Kirsch et al., 2002). Defenders of antidepressant medications argue that even relatively small effects are better than none (e.g., Thase, 2002), while critics contend that those effects are too small to matter, especially when viewed in light of these drugs' high cost and potential adverse side effects (e.g., Breggin, 2008; Moncrieff & Kirsch, 2005; Wampold et al., 2005).

Lithium and Anticonvulsants In 1949, J. F. Cade discovered that a mineral salt of the element *lithium,* when taken regularly, could prevent the mania associated with bipolar disorder in some patients (Schou, 2001). In fact, for 30 to 50 percent of patients with bipolar disorder, lithium is effective in preventing both manic and depressive episodes, thereby earning its label as a *mood stabilizer* (Geddes et al., 2004; Schatzberg, Cole, & DeBattista, 2007). Without lithium, the typical bipolar patient has a manic episode about every fourteen months and a depressive episode about every seventeen months (American Psychiatric Association, 2000). With lithium, attacks of mania occur as rarely as every nine years (Bowden, 2000; Geddes et al., 2004). The lithium

antidepressant drugs Medications that relieve depression.

dosage must be exact and carefully controlled, however, because taking too much can cause nausea, vomiting, tremor, fatigue, slurred speech, and, if the overdose is severe, coma or death (Johnson, 2002). Further, lithium is not useful for treating a manic episode in progress because, as in the case of antidepressant drugs, it takes a week or two of regular use before its effects are seen. So as with the antidepressants, the effects of lithium probably occur through some form of long-term adaptation as the nervous system adjusts to the presence of the drug. Combining lithium with other mood-stabilizing drugs, such as carbamazepine, has shown enhanced benefits but also more adverse side effects (Baethge et al., 2005).

In recent years, anticonvulsant drugs such as *divalproex* (Epival, Depakote) and *lamotrigine* (Lamictal) have been used as an alternative to lithium in treating mania (e.g., Daban et al., 2006; Delbello et al., 2006). These drugs cause fewer side effects than lithium, are less dangerous at higher doses, and are easier to regulate (Bowden, 2000, 2003; Schatzberg, Cole, & DeBattista, 2007). However, their long-term benefits in reducing mania and the risk of suicide are not as well established, so lithium is still considered the treatment of choice against which other medications are measured (Calabrese et al., 2005; Capriani et al., 2005; McAllister-Williams, 2006).

Tranquilizing Drugs (Anxiolytics) During the 1950s, a new class of drugs called *tranquilizers* was shown to reduce mental and physical tension and other symptoms of anxiety. The first of these drugs, called *meprobamate* (Miltown, Equanil), acts somewhat like barbiturates, meaning that overdoses can be fatal (Allen, Greenblatt, & Noel, 1977). Newer tranquilizers, known as *benzodiazepines*—such as *chlordiazepoxide* (Librium) and *diazepam* (Valium)—do not pose this danger and have become the worldwide drugs of choice for the treatment of anxiety (Stevens & Pollack, 2005). Today, these and other antianxiety drugs, now called **tranquilizing drugs**, or **anxiolytics** (pronounced "ank-zee-oh-LIT-iks"), continue to be the most widely prescribed of all legal drugs (Stevens & Pollack, 2005). Anxiolytics have an immediate calming effect and are quite useful in reducing anxiety, including in cases of generalized anxiety disorder and posttraumatic stress disorder.

One of the benzodiazepines, *alprazolam* (Xanax), has become especially popular for the treatment of panic disorder and agoraphobia (Verster & Volkerts, 2004). Another benzodiazepine, *clonazepam* (Klonopin), is also being used, alone or in combination with other anxiolytics, in the treatment of anxiety ranging from phobias to panic disorder. But benzodiazepines can have bothersome side effects such as sleepiness, lightheadedness, and impaired psychomotor and mental functioning. Combining these drugs with alcohol can be fatal, and continued use can lead to tolerance and physical dependence (Chouinard, 2004). Furthermore, suddenly discontinuing benzodiazepines after heavy or long-term use can cause severe withdrawal symptoms, including seizures and anxiety attacks (Lemoine et al., 2006; Rickels et al., 1993).

The tranquilizing drug *buspirone* (BuSpar) provides an alternative anxiety treatment that eliminates some of these problems. As with antidepressant drugs, buspirone's effects do not occur for days or weeks after treatment begins. As a result, many patients stop taking it because they think it has no effect other than dizziness, headache, and nervousness (Stahl, 2002; Wagner et al., 2003). Yet buspirone can ultimately equal benzodiazepines in reducing generalized anxiety (Gorman, 2003; Rickels & Rynn, 2002). Further, it does not seem to promote dependence, has fewer side effects than the benzodiazepines, and does not interact dangerously with alcohol.

Because depression often accompanies anxiety, antidepressant drugs such as fluoxetine (Prozac), paroxetine (Paxil), clomipramine (Anafranil), fluvoxamine (Luvox), and sertraline (Zoloft) are also used in treating anxiety-related problems such as panic disorder, social phobia, obsessive-compulsive disorder, and posttraumatic stress disorder (e.g., Gorman, 2003; Julien, 2008; Nutt, 2005b; Rickels et al., 2003). Table 16.5 lists the effects and side effects of the psychoactive medications we have described.

tranquilizing drugs (anxiolytics) Drugs that reduce feelings of anxiety.

TABLE 16.5 A Sampling of Psychoactive Drugs Used for Treating Psychological Disorders

Psychoactive drugs have been successful in dramatically reducing the symptoms of many psychological disorders. Critics point out that drugs can have troublesome side effects, however, and they may create dependence, especially after years of use (e.g., Breggin, 2008). They note, too, that drugs do not "cure" mental disorders, that their effects are not always strong, and that temporary symptom relief may make some patients less likely to seek a permanent solution to their psychological problems.

Chemical Name	Trade Name	Effects and Side Effects
For Schizophrenia: Neuroleptic Drugs (Antipsychotics)		
Chlorpromazine Haloperidol	Thorazine Haldol	Reduce hallucinations, delusions, incoherence, and jumbled thought processes but may cause movement disorder side effects, including tardive dyskinesia
Clozapine	Clozaril	Reduces psychotic symptoms; causes no movement disorders but carries some risk of serious blood disease
Risperidone	Risperdal	Reduces positive and negative psychotic symptoms without risk of blood disease
Ziprasidone	Geodon	Reduces positive and negative psychotic symptoms without causing weight gain
Aripiprazole	Abilify	Reduces positive and negative psychotic symptoms without weight gain and with few side effects
For Affective Disorders: Antidepressant Drugs and Mood Elevators		
Tricyclics		
Imipramine	Tofranil	Act as antidepressants but also have antipanic action; cause sleepiness and other moderate side effects; potentially dangerous if taken with alcohol
Amitriptyline	Elavil, Amitid	
Other Antidepressant Drugs		
Fluoxetine	Prozac	Have antidepressant, antipanic, and antiobsessive action
Clomipramine	Anafranil	
Fluvoxamine	Luvox	
Sertraline	Zoloft	
Escitalopram	Lexapro	
Other Drugs		
Lithium carbonate	Carbolith, Lithizine	Calms mania; reduces mood swings of bipolar disorder; overdose harmful, potentially deadly
Divalproex	Depakote	Is effective against mania, with fewer side effects
Lamotrigine	Lamictal	Is effective in delaying relapse in bipolar disorder; most benefits associated with depression
For Anxiety Disorders: Tranquilizing Drugs (Anxiolytics)		
Benzodiazepines		
Chlordiazepoxide Diazepam	Librium Valium	Act as potent anxiolytics for generalized anxiety, panic, and stress; extended use may cause physical dependence and withdrawal syndrome if abruptly discontinued
Alprazolam	Xanax	Also has antidepressant effects; often used in agoraphobia; has high dependence potential
Clonazepam	Klonopin	Often used in combination with other anxiolytics for panic disorder
Other Antianxiety Agents		
Buspirone	BuSpar	Has slow-acting antianxiety action; no known dependence problems

Human Diversity and Drug Treatment Prescription drug treatments are designed to benefit everyone in the same way ("In Review: Biological Treatments for Psychological Disorders" summarizes our discussion of drugs and other biological treatments), but it turns out that the same amount of medication can have significantly different effects in people from various ethnic groups and in men versus women (e.g., Esel et al., 2005; Lambert & Norman, 2008; Seeman, 2004). For example, compared with Asians, Caucasians must take significantly higher doses of the benzodiazepines, haloperidol, clozapine, lithium, and possibly the tricyclic antidepressants in order to

IN REVIEW Biological Treatments for Psychological Disorders

Method	Typical Disorders Treated	Possible Side Effects	Mechanism of Action
Electroconvulsive shock therapy (EST)	Severe depression	Temporary confusion, memory loss	Uncertain
Psychosurgery	Schizophrenia, severe depression, obsessive-compulsive disorder	Listlessness, overemotionality, epilepsy	Uncertain
Psychoactive drugs	Anxiety disorders, depression, obsessive-compulsive disorder, mania, schizophrenia	Variable, depending on drug used: movement disorders, physical dependence	Alteration of neurotransmitter systems in the brain

1. **Electroconvulsive shock therapy is used ___________ often now than it was in the 1950s.**
2. **Tranquilizing drugs are used mainly in the treatment of ___________.**
3. **Tardive dyskinesia is a movement disorder sometimes caused by ___________ drugs.**

obtain equally beneficial effects (Hull et al., 2001; Ng et al., 2005). In addition, African Americans may show a faster response to tricyclic antidepressants than European Americans and may respond to lower doses of lithium (Chaudhry et al., 2008). There is also some evidence that compared with European Americans or African Americans, Hispanic Americans require lower doses of antipsychotic medication to get the same benefits (Citrome et al., 2005). Some of these ethnic differences are thought to be related to genetically regulated differences in drug metabolism (Kato & Serretti, 2010; Zhang, Lencz, & Malhotra, 2010); others may be due to dietary practices and other sociocultural factors (Bakare, 2008).

Males and females may respond in about the same way to tricyclic antidepressants (Wohlfarth et al., 2004), but women may maintain higher blood levels of these and other therapeutic psychoactive drugs and may show better response to neuroleptic drugs (Hildebrandt et al., 2003; Salokangas, 2004). They also may be more vulnerable to adverse effects such as tardive dyskinesia (Yarlagadda et al., 2008). These gender differences in response to medication appear less related to estrogen than to other hormonal or body composition differences between men and women, such as the ratio of body fat to muscle (Salokangas, 2004). Continued research on these and other dimensions of human diversity will undoubtedly lead to more effective and safer drug treatments for everyone (Thompson & Pollack, 2001).

Evaluating Psychoactive Drug Treatments

Despite the widespread success of psychoactive prescription drugs in the treatment of psychological disorders, critics point out several shortcomings. First, drugs may suppress a client's disorder without eliminating it. As a result, the client may be less likely to try nondrug approaches that might lead to permanent benefits. Antianxiety drugs, for example, can help clients to feel calmer, but these medications alone cannot teach people to cope with the sources of their anxiety. There is concern that psychiatrists, and especially general practitioners, rely too heavily on anxiolytics and other medications to solve their patients' psychological problems (Breggin, 2008; Mojtabai & Olfson, 2010). The antidepressant drug Prozac, for instance, is being widely prescribed—overprescribed, critics say—for problems ranging from hypersensitivity to criticism and fear of rejection to low self-esteem and premenstrual problems (Breggin, 2008). Second, abuse of some drugs (such as the antianxiety benzodiazepines) can result in physical or psychological dependence. Third, drug side effects can range from minor problems, such as the thirst and dry mouth caused by some antidepressant drugs, to movement disorders such as tardive dyskinesia caused by certain neuroleptic drugs. The most serious of these side effects are relatively rare, but some are irreversible, and it is impossible to predict in advance who will develop them. Although a clear causal link has not been confirmed (Gibbons et al., 2005; Simon et al., 2006; Wheeler et al., 2008), recent research has led the

There is widespread concern that psychiatrists and especially general practitioners rely too heavily on drugs to deal with psychological problems, including those of adolescents and children (Albee, 2002; Breggin, 2008; Olfson et al., 2006; Zuvekas, Vitiello, & Nordquist, 2006). This trend appears due in part to drug ads that fuel consumer demand, but drugs are not always the answer. In one case, for example, increasing doses of medication failed to stop a paranoid schizophrenia patient's repeated escapes from a mental hospital. The problem was solved without drugs, though, after a psychologist discovered that the man's escapes were motivated by his fear of calling his mother on "bugged" hospital phones; once he was allowed to use a telephone at a nearby shopping mall, his escape attempts stopped (Rabasca, 1999).

"I medicate first and ask questions later."

National Institute of Mental Health (NIMH) in the United States and regulatory agencies in Canada and Britain to issue warnings about the danger of suicidal behavior in children and adolescents who are given Prozac and similar antidepressant drugs (Bridge et al., 2007; Breggin, 2008; Gualtieri & Johnson, 2006; Hammad, Laughren, & Racoosin, 2006; NIMH, 2004; Olfson, Marcus, & Shaffer, 2006; Stone et al., 2009). Warnings have also been issued about the elevated risk of death in elderly patients who are taking antipsychotic medications (U.S. Food and Drug Administration, 2005; Wang, Schneeweiss, et al., 2005). There is concern, too, about whether psychoactive medications are as effective as they appear to be, especially in research sponsored by the drug companies that make them (Heres et al., 2006; Moncrieff & Kirsch, 2005; Turner et al., 2008). These concerns may be dampening the enthusiasm that once led many psychologists to seek drug prescription privileges (Greenberg, 2010).

Drugs and Psychotherapy

Which is better, drugs or psychotherapy? Are the two more effective when combined? A considerable amount of research is being conducted to address these questions.

Although occasionally a study does show that one approach or the other is more effective, no clear consensus has emerged. Overall, neither form of therapy is clearly superior for treating problems such as anxiety disorders and major depressive disorder (Smits, O'Cleirigh, & Otto, 2006; Thase et al., 2007). For example, large-scale studies of treatment for severe depression found that behavior therapy, cognitive behavior therapy, and interpersonal psychotherapy can be as effective as an antidepressant medication (Butler et al., 2006; DeRubeis et al., 2005; Dimidjian et al., 2006; Hollon, Thase, & Markowitz, 2002; March et al., 2004; Nemeroff et al., 2003). Cognitive behavior therapy has also equaled the effects of medication in the treatment of phobias (Clark et al., 2003; Davidson et al., 2004; Otto et al., 2000; Thom, Sartory, & Jöhren, 2000), panic disorder (Barlow, 2007; Mitte, 2005a), generalized anxiety disorder (Mitte, 2005b), and obsessive-compulsive disorder (Kozak, Liebowitz, & Foa, 2000). Further, the dropout rate from psychotherapy may be lower than from drug therapies (Casacalenda, Perry, & Looper, 2002; Hollon et al., 2005; Mitte, 2005b), and the benefits of many kinds of psychotherapy may last longer than those of drug treatments (e.g., Bockting et al., 2005; Hollon, Stewart, & Strunk, 2006; Hollon, Thase, & Markowitz 2002; Segal, Gemar, & Williams, 2000; Thom, Sartory, & Jöhren, 2000), thus making psychotherapy more cost-effective than medication in the long run (Barrett, Byford, & Knapp, 2005).

What about combining prescription drugs and psychotherapy? Research suggests that doing so can sometimes be helpful (Hofmann et al., 2006; Miklowitz et al., 2007; Winston, Been, & Serby, 2005). Combined treatment is recommended in cases of bipolar disorder (Miklowitz, 2008; Otto, Smits, & Reese, 2005) and produces slightly better results than either psychotherapy or drugs alone in people suffering from severe, long-term depression (Friedman et al., 2004; Hegerl, Plattner, & Moller, 2004). The combination of medication and psychotherapy has also been shown to be more effective than either method alone in treating attention deficit hyperactivity disorder, obsessive-compulsive disorder, alcoholism, stammering, compulsive sexual behavior, and panic disorder (Barlow, 2007; Keller et al., 2000; March et al., 2004; Roy-Byrne et al., 2005; Walkup et al., 2008). The combined approach may be especially useful for clients who are initially too distressed to benefit much from psychotherapy. A related approach, already shown to be successful with clients who had been taking prescription drugs for panic disorder and depression, is to use psychotherapy to prevent relapse and make further progress as medication is discontinued (e.g., Dobson et al., 2008; Klein et al., 2004; Lam et al., 2003). Preliminary evidence also suggests that a drug called D-cycloserine may be helpful in preventing the reappearance of fears that are being extinguished through exposure techniques or other forms of behavior therapy (Choy, Fyer, & Lipsitz, 2007; Davis, Myers, et al., 2005; Davis et al., 2006; Hofmann et al., 2006; Norberg, Krystal, & Tolin, 2008).

However, many other studies have found little advantage in combining medication and psychotherapy (e.g., Davidson et al., 2004; Elkin, 1994; Nemeroff et al., 2003; Spiegel & Bruce, 1997). One early study compared the effects of a form of in vivo desensitization called *gradual exposure* with that of antianxiety medication (Xanax) in the treatment of agoraphobia. Clients receiving gradual exposure alone showed better short- and long-term benefits than those getting either the drug alone or a combination of the drug and gradual exposure (Echeburua et al., 1993). Other studies, too, have found that combining drugs and psychotherapy may produce surprisingly little added benefit (e.g., Elkin, 1994; Spiegel & Bruce, 1997).

Perhaps the most conservative strategy for treating most cases of anxiety and depression is to begin with cognitive or interpersonal psychotherapy (which have no major negative side effects) and then to add or switch to medication if psychotherapy alone is ineffective (Jacobs et al., 2004; Schatzberg et al., 2005). Often clients who do not respond to one method will be helped by the other (e.g., Heldt et al., 2006). Someday research may offer better guidelines as to which clients should be treated with psychotherapy alone, medication alone, or a combination of the two (Hollon et al., 2005).

LINKAGES How do psychoactive drugs work? (a link to Biological Aspects of Psychology, p. 68)

Biological Aspects of Psychology and the Treatment of Psychological Disorders

As described in the chapter on biological aspects of psychology, human feelings, thoughts, and actions—whether normal or abnormal—are ultimately the result of biological processes, especially those involving neurotransmitters and their receptors in the brain. Because different neurotransmitters are especially prominent in particular brain regions or circuits, altering the functioning of particular neurotransmitter systems has relatively specific psychological and behavioral effects.

Let's consider some of the ways in which therapeutic psychoactive drugs affect neurotransmitters and their receptors. Some therapeutic drugs cause neurons to fire, while others reduce or inhibit such firing. For example, benzodiazepines (e.g., Valium and Xanax) exert their antianxiety effects by helping the inhibitory neurotransmitter GABA bind to receptors and thus suppress neuron firing. This increased inhibitory effect acts as a sort of braking system that slows the activity of GABA-sensitive neurons involved in the experience of anxiety. However, benzodiazepines also slow the action of all neural systems that use GABA, including those associated with motor activity and mental processing, which are spread throughout the brain. The result is the decreased motor coordination and clouded thinking that appear as the side effects of the benzodiazepines. Research suggests that it may soon be possible to develop drugs that will bind only to certain kinds of GABA receptors and thus greatly reduce these side effects (Gorman, 2005).

LINKAGES How do drugs help people diagnosed with schizophrenia? (a link to Consciousness" p. 356)

Other therapeutic drugs are receptor *antagonists* (see Figure 9.10 in the chapter on consciousness), acting to block the receptor site normally used by a particular neurotransmitter. The phenothiazines, for example, exert their antipsychotic effects by blocking receptors for dopamine, a neurotransmitter that is important for movement, as described in the chapter on biological aspects of psychology. Blocking dopamine seems to normalize the jumbled thinking of many schizophrenia patients, but it can also cause severe disorders—including tardive dyskinesia—in the movement systems that are also controlled by dopamine.

Some psychoactive drugs exert their therapeutic influence by increasing the amount of a neurotransmitter available to act on receptors. This effect usually occurs because the drug slows a process called *reuptake,* by which the neurotransmitter would normally return to the brain cell from which it was released. The tricyclic antidepressants, for example, operate by slowing the reuptake of norepinephrine. Prozac, Anafranil, and some other antidepressant drugs are called *selective serotonin reuptake inhibitors* (*SSRIs*) because they slow the reuptake of serotonin. Others, such as Effexor, slow the reuptake of both serotonin and norepinephrine. These effects are consistent with biological theories suggesting that some cases of depression are traceable to faulty norepinephrine or serotonin systems.

Community Psychology: From Treatment to Prevention

It has long been argued that even if psychologists knew exactly how to treat every psychological problem, there would never be enough mental health professionals to help everyone who is in need (Albee, 1968, 2006). A study by the World Health Organization found, for example, that even individuals with severe mental health problems often do not receive the psychological services they need (Wang et al., 2007). The study also revealed that the treatment situation is especially dire in poorer countries, where only about 11 percent of psychologically troubled individuals receive treatment for their disorders. In high-income countries such as the United States and Belgium, the figure was about 60 percent (see also Gonzalez et al., 2010). Even that percentage is too low, though, and recognition of the treatment access problem helped fuel the rise of **community psychology**, which seeks to treat people in their local communities and work for social changes that can help prevent psychological disorders (Nelson & Prilleltensky, 2004).

One aspect of community psychology, the *community mental health movement,* appeared during the 1960s amid growing concern that patients were not improving (and might be getting worse) after years of confinement in mental hospitals. The idea behind this movement was that these hospitalized patients would be better off if they were allowed to live freely in their communities, where they would receive newly available antipsychotic drugs and other mental health services at a network of community mental health centers. This *deinstitutionalization* process did spare thousands of patients the boredom and isolation of the hospital environment, but the mental health

Community Mental Health Efforts

APPLYING PSYCHOLOGY

Professional and nonprofessional staff members of community mental health centers provide traditional therapy and mental health education, along with walk-in facilities and hotlines for people who are suicidal or in crises because of rape or domestic violence. They also offer day treatment to former mental patients, many of whom are homeless.

services available in their communities never expanded enough to meet the needs of so many new clients (Leff, 2006). Some former hospital patients and many people whose disorders might once have sent them to mental hospitals are now living in halfway houses and other community-based facilities where they receive *psychosocial rehabilitation*. These community support services are not designed to "cure" disorders but rather to help people cope with their problems and develop the social and occupational skills necessary for semi-independent living (Coldwell & Bender, 2007; Cook et al., 2005; Talbott, 2004). Many patients with severe psychological disorders who have not received or benefited from rehabilitation services are enduring the dangers of homelessness on city streets or of confinement in jails and prisons (Luhrmann, 2008; Smith & Sederer, 2009; Teplin et al., 2005).

Community psychology also attempts to prevent psychological disorders by addressing poverty, substandard housing, and other stressful social problems that may put vulnerable people at greater risk for some disorders (Fagan et al., 2009; Xue et al., 2005). Researchers in the field of positive psychology applaud this approach, suggesting that the development of many disorders could be further minimized by teaching skills that promote mental well-being and by offering programs designed to help young people build the character strengths they need to be resilient in the face of stress (Keyes, 2007; Seligman, Berkowitz et al., 2005; Wallace & Shapiro, 2006).

Another dimension of community psychology involves efforts to detect psychological problems in their earliest stages and keep those problems from becoming worse (Bond & Hauff, 2004). Examples include programs for the prevention of depression and suicide (Cuijpers et al., 2008; Gillham et al., 2007; Horowitz & Garber, 2006; Lynch et al., 2005; Spence, Sheffield, & Donovan, 2005), programs such as Project Head Start that help preschoolers whose backgrounds put them at risk for school failure and delinquency (Foster et al., 2006; Reid, Webster-Stratton, & Baydar, 2004; Shaw, Dishion, et al., 2006), and programs to identify children who are at risk for disorders due to aggressiveness, parental divorce, or being rejected or victimized at school (e.g., Frey et al., 2005; Lochman & Wells, 2004; Martinez & Forgatch, 2001). Other interventions are designed to head off anxiety disorders or schizophrenia in children and adults (McGorry et al., 2002; Neil & Christensen, 2009; Rapee et al., 2005), to prevent child abuse and other domestic violence (Duggan et al., 2004; Whitaker et al., 2006), and to promote health consciousness in ethnic minority communities (Borg, 2002).

LINKAGES

As noted in the chapter on introducing psychology, all of psychology's many subfields are related to one another. Our discussion of treating psychological disorders through the use of psychoactive drugs illustrates just one way in which the topic of this chapter, the treatment of psychological disorders, is linked to the subfield of biological psychology (see the chapter on biological aspects of psychology). The Linkages diagram shows ties to two other subfields as well, and there are many more ties throughout the book. Looking for linkages among subfields will help you see how they all fit together and better appreciate the big picture that is psychology.

CHAPTER 13
Health, Stress, and Coping

SUMMARY

Psychotherapy for psychological disorders is usually based on psychodynamic, humanistic, or social-cognitive (behavioral) theories of personality and behavior disorder. Most therapists combine features of these theories in an eclectic approach. The biological approach is reflected in the use of prescription drugs and other physical treatment methods.

Basic Features of Treatment

All forms of treatment for psychological disorders include a client, a therapist, an underlying theory of behavior disorder, a set of treatment procedures suggested by the underlying theory, and the development of a special relationship between the client and therapist, which may make it easier for improvement to occur. Therapy may be offered to inpatients and outpatients in many different settings by *psychologists, psychiatrists,* and other mental health professionals. The goal of treatment is to help people change their thinking, feelings, and behavior so that they will be happier and function better. This goal may be pursued by promoting insight into hidden causes of behavior problems, by fostering personal growth through genuine self-expression, or by helping clients learn new ways of thinking and acting.

Psychodynamic Psychotherapy

Psychodynamic psychotherapy, which began with Sigmund Freud's methods of *psychoanalysis,* seeks to help clients gain insight into unconscious conflicts and impulses and then to explore how those factors have created disorders.

Classical Psychoanalysis

Exploration of the unconscious is aided by the use of free association, dream interpretation, and analysis of transference.

Contemporary Variations on Psychoanalysis

Some variations on psychoanalysis focus less on the id, the unconscious, and the past and more on helping clients harness the ego to solve problems in the present. Other forms of psychodynamic treatment retain most of Freud's principles but use a more flexible format. Object relations therapy, for example, examines the effects of early relationships with caregivers and how those relationships affect current ones.

Humanistic Psychotherapy

Humanistic (phenomenological) psychotherapy helps clients become more aware of discrepancies between their feelings and their behavior. According to the humanistic approach, these discrepancies are at the root of behavior disorders and can be resolved by the client once they are brought to light in the context of a genuine, trusting relationship with the therapist.

Client-Centered Therapy

Therapists using Carl Rogers's *client-centered therapy,* also known as *person-centered therapy,* help mainly by adopting attitudes toward the client that express *unconditional positive regard (acceptance), empathy*, and *congruence.* These attitudes create a nonjudgmental atmosphere that facilitates the client's honesty with the therapist, with himself or herself, and with others. One way of creating this atmosphere is through *active listening (reflection).*

Gestalt Therapy

Therapists employing the *Gestalt therapy* of Fritz and Laura Perls use more active techniques than Rogerian therapists, often confronting and challenging clients.

Behavior Therapy

Behavior therapy, behavior modification, and *cognitive behavior therapy* use learning principles to reduce clients' undesirable patterns of thought and behavior and to strengthen more desirable alternatives.

Techniques for Modifying Behavior

Common behavioral treatments include *systematic desensitization therapy, flooding* and other *exposure therapy* techniques, *modeling, social skills training,* and *assertiveness training.* Behavior therapists also use *positive reinforcement* (sometimes in *token economy programs*), *extinction, punishment*, and *aversion conditioning* to make desirable behaviors more likely or problematic behaviors less likely.

Cognitive Behavior Therapy

Many behavior therapists employ cognitive behavior therapy to help clients change the way they think, as well as the way they behave. Among the specific cognitive behavior therapy methods are *rational-emotive behavior therapy* (*REBT*), cognitive restructuring, stress inoculation training, and *cognitive therapy.*

Group, Family, and Couples Therapy

Therapists of all theoretical persuasions may offer therapy to several clients at once. Clients' interactions with one another can enhance the effects of treatment.

Group Therapy

Group therapy may involve a variety of people and problems, or it may focus on particular types of clients and problems. The group format is also adopted in many self-help organizations, such as Alcoholics Anonymous.

Family and Couples Therapy

Family therapy involves treatment of two or more individuals from the same family system. In *couples therapy,* the clients are spouses or other intimate partners. In both formats, treatment usually focuses on improving communication and other interactions among the people involved.

Evaluating Psychotherapy

There is some disagreement about exactly how to measure improvement following psychotherapy and how best to ensure that observed improvement was actually due to the treatment itself and not to some other factor. Meta-analyses have found that clients who receive psychotherapy are better off than most people who receive no treatment but that no single approach is uniformly better than all others for all clients and problems. Still, some methods appear effective enough in the treatment of particular disorders to have been listed by an American Psychological Association task force as *empirically supported therapies* (*ESTs*) that can guide *evidence based practice.*

Research is still needed to discover which combinations of therapists, clients, and treatments are ideally suited to alleviating particular psychological problems. Several factors, including personal preferences, must be considered when choosing a treatment approach and a therapist.

Sociocultural Factors in Psychotherapy

The effects of cultural differences in values and goals between therapist and client have attracted increasing attention. Efforts are under way to minimize the problems that these differences can create.

Rules and Rights in the Therapeutic Relationship

Whatever the specific form of treatment, the client's rights include the right to confidentiality, the right to receive or refuse treatment, and the right to protection from unnecessary confinement.

Biological Treatments

Biological treatment methods seek to relieve psychological disorders by physical rather than psychological means.

Psychosurgery

Psychosurgery procedures once involved mainly prefrontal lobotomy; when used today, usually as a last resort, they focus on more limited areas of the brain.

Electroconvulsive Shock Therapy

In *electroconvulsive shock therapy* (*EST*), an electric current is passed through the patient's brain, usually in an effort to relieve severe depression.

Psychoactive Drugs

Today the most prominent form of biological treatment is the prescription of psychoactive drugs, including those used to treat schizophrenia (the *neuroleptic drugs,* or antipsychotics), affective disorders (*antidepressant drugs, lithium,* and *anticonvulsants*), and anxiety disorders (*tranquilizing drugs,* or *anxiolytics*). There appear to be significant differences among members of various ethnic groups and between men and women in the dosages of psychoactive drugs necessary to produce beneficial effects.

Evaluating Psychoactive Drug Treatments

Psychoactive drugs have proved impressively effective in many cases, but critics point out a number of undesirable side effects associated with these drugs, the risks of abuse, and the dangers of overreliance on chemical approaches to human problems that might have other solutions.

Drugs and Psychotherapy

So far, neither psychotherapy nor drug treatment has been found clearly superior overall for treating problems such as anxiety or depression. Combining drugs and psychotherapy may help in some cases, but their joint effect may not be any greater than the effect of either one alone.

Community Psychology: From Treatment to Prevention

The realization that there will never be enough therapists to treat everyone who needs help prompted the development of *community psychology.* Community mental health programs and efforts to prevent mental disorders are the two main elements of community psychology.

LINKAGES TO FURTHER LEARNING

Now that you have finished reading this chapter, how about exploring some of the topics and information that you found most interesting? Here are some places to start.

Books

Peter Wyden, *Conquering Schizophrenia: A Father, His Son, and a Medical Breakthrough* (Knopf, 1998). A father searches for a cure for his son, who was diagnosed with schizophrenia.

Ken Kesey, *One Flew over the Cuckoo's Nest* (New American Library, 1989). The book about life in a mental hospital from which the award-winning movie was adapted.

Michael Winerip, *9 Highland Road* (Vintage, 1995). The aftermath of deinstitutionalization.

Peter Kramer, *Listening to Prozac* (Penguin, 1997). Psychotropic antidepressant medications.

Raymond J. Corsini and Danny Wedding, *Current Psychotherapies*, 9th ed. (Brooks Cole, 2010) A comparison of numerous approaches to psychotherapy.

Frank Dumont and Raymond J. Corsini (Eds.), *Six Therapists and One Client* (Springer, 2000). Therapists who represent different treatment approaches describe how they would help the same client.

W. S. Appleton, *Prozac and the New Antidepressants: What You Need to Know About Prozac, Zoloft , Paxil, Luvox, Wellbutrin, Effexor, Serzone, Vestra, Celexa, St. John's Wort, and Others,* rev. ed. (Plume Books, 2000). A summary of drug treatment options for depression.

Christina Hoff Summers and Sally Satel, *One Nation Under Therapy: How the Helping Culture Is Eroding Self-Reliance* (St. Martin's Press, 2005). Argues that people have become overly dependent on psychotherapy.

TALKING POINTS

Here are a few talking points to help you summarize this chapter for family and friends without giving a lecture.

1. All forms of psychotherapy include a client, a helper, and a special therapeutic relationship.
2. Psychiatrists are medical doctors who specialize in psychological disorders; psychologists who study or treat such disorders usually have Ph.D. degrees in clinical or counseling psychology.
3. Classical Freudian psychoanalysis is no longer the dominant approach to psychotherapy in North America.
4. Many kinds of psychotherapy can be beneficial, but experimental research has shown behavior therapy, cognitive behavior therapy, and interpersonal therapy to be among the most effective forms of treatment for many psychological disorders.
5. When looking for a therapist, people should select one who seems easy to relate to and who has experience with a treatment approach that is known to be effective for their type of problem.
6. With only a few special exceptions, therapists are ethically bound to keep confidential everything that clients tell them.
7. Prescription drugs and psychotherapy are often equally effective in the treatment of many psychological disorders.

SUMMARY

Your view of yourself and what you think about others play major roles in shaping your behavior every day. In this chapter, we explore the ways in which perception, learning, emotion, and other factors affect how people think about themselves and others. We'll consider topics such as how we form first impressions, how we develop attitudes—including prejudiced attitudes—and why we may like (or love) one person and dislike another.

The terrorist attacks of 9/11 killed nearly 3,000 people and had Umar Farouk Abdulmutallab succeeded in detonating the bomb he carried aboard a Northwest Airlines flight on Christmas Day, 2009, hundreds more would have died. Almost all of the questions that can be asked about these attacks, and about the continuing threat of terrorism in general, relate to human behavior. For example, what could lead people to kill themselves, along with untold numbers of innocent people, in the name of political or religious beliefs? Why did so many New York City firefighters, police officers, emergency medical workers, and others enter the World Trade Center's burning towers to save the lives of others while risking and some ultimately losing their own? Why did some of the people who were fleeing the damaged buildings return to their offices after hearing an announcement telling them to do so? Is there any reason to hope that someday the hatred and distrust that fuels terrorism can be reduced or eliminated?

We may never have final answers to such questions, but some partial answers may come from **social psychology**, the scientific study of how people's thoughts and feelings influence their behavior toward others and how the behavior of others influences people's own thoughts, feelings, and behavior. In this chapter, we focus on **social cognition**, the mental processes associated with the ways in which people perceive and react to other individuals and groups (Fiske & Taylor, 2008). Specifically, we will examine how people think about themselves and others, how they form and change attitudes, why and how they use stereotypes to judge other people (sometimes in unfair and biased ways), and why they like or dislike other people. In the companion chapter on *social influence,* we describe how social factors affect individuals, shaping behaviors that range from despicable acts of aggression to inspiring acts of heroism and self-sacrifice.

Social Influences on the Self

In the chapters on human development and personality, we describe how each individual develops within a cultural context and the ways in which collectivist and individualist cultures emphasize different core values and encourage contrasting definitions of the self. In this section, we highlight the processes through which people in each culture help shape two important components of the self. The first is our **self-concept**, the thoughts, feelings, and beliefs we hold about who we are and what characteristics we have. The second is our **self-esteem**, the evaluations we make about how worthy we are as human beings (Crocker et al., 2006).

social psychology The study of how people's thoughts, feelings, and behavior influence and are influenced by the behavior of others.

social cognition Mental processes associated with people's perceptions of and reactions to other people.

self-concept The way one thinks of oneself.

self-esteem The evaluations one makes about how worthy one is as a human being.

Social Comparison

People spend a lot of time thinking about themselves, trying to evaluate their own perceptions, opinions, values, and abilities (Epstude & Mussweiler, 2009). Decades ago, Leon Festinger (1954) pointed out that self-evaluation involves two types of questions: those that can be answered by taking objective measurements and those that cannot. So you can determine your height or weight by measuring it, but how do you answer questions about your cognitive ability, social skills, athletic talent, or the quality of your relationships? Here there are no yardsticks to act as objective measurement criteria. In these cases, we make one of two types of comparisons. If we use a *temporal comparison*, we consider the way we are now in relation to how we were in the past (Zell & Alicke, 2009). If we use a **social comparison**, we evaluate ourselves in relation to others. So if you use others as a basis for evaluating how intelligent, athletic, interesting, or attractive you are, you are using social comparison (Buunk et al., 2005).

Who serves as your basis of comparison? Festinger said that people usually look to others who are similar to themselves. If you are curious about how good a swimmer you are, you are likely to compare yourself with the people you normally compete against, not with Olympic champions. In other words, you tend to choose swimmers at your own level of experience and ability. The categories of people to which you see yourself belonging and to which you usually compare yourself are called **reference groups**.

The performance of people in a reference group can influence your self-esteem (Chambers & Windschitl, 2009). For example, if being a good swimmer is very important to you, knowing that someone in your reference group swims much faster than you do can lower your self-esteem. People use a wide variety of strategies to protect or maintain their self-esteem (Greenberg, 2008; Leary, 2010). Sometimes they choose to compare themselves with those who are not as good as they are, a strategy called *downward social comparison*. They may also engage in *upward social comparison,* comparing themselves with people who do much better (Johnson & Stapel, 2007). Both kinds of social comparisons can make people feel better about themselves. Downward social comparisons remind them that although their performance or their lives may not be ideal, things could be worse. The comfort provided by such reminders helps explain the popularity of Jerry Springer and other television shows featuring guests who are stuck in unpleasant, dysfunctional, and often bizarre family situations. But sometimes people may feel better after comparing themselves with those who are doing much better than they are (Wheeler & Suls, 2007). This result occurs partly because seeing people who are better off than we are can inspire the belief that "if they can do it, so can I!" (Buunk, Peiró, & Griffioen, 2007). And people's performance often does improve following upward social comparison (Johnson & Stapel, 2007).

Some people use a related tactic to maintain their self-esteem through upward social comparison. Specifically, they tell themselves that a superior performer is not similar enough to be in their reference group. They may even exaggerate the ability of the other person so that their own performance doesn't look so bad when viewed in light of such an able competitor (Mussweiler, 2003). If you can convince yourself that you lost every set in a tennis game because your opponent is almost as good as Roger Federer, Serena Williams, or some other world-class tennis player, then it is easier to believe that your performance wasn't so terrible and that you would do just fine against someone with normal athletic skills.

An unfavorable comparison of your own status with that of others can produce a sense of **relative deprivation**—the belief that no matter how much you are getting in terms of recognition, status, money, and other rewards, it is less than you deserve (Kassin, Fein, & Markus, 2010). The concept of relative deprivation explains why an actor who receives $5 million to star in a film feels slighted if a costar is receiving $10 million. It also explains the far more common situation in which employees become dissatisfied when they consider themselves underpaid or underappreciated in comparison to their coworkers (Harris, Anseel, & Lievens, 2008). When large groups of people experience relative deprivation, political unrest may follow. Social and political turmoil usually begins after the members of a deprived group experience some improvement in their lives and begin to compare their circumstances with those in other groups (de la Sablonnière, Tougas, & Lortie-Lussier, 2009). With this improvement come higher expectations about what they deserve. When these expectations

social comparison Using other people as a basis of comparison for evaluating oneself.

reference groups Categories of people to which people compare themselves.

relative deprivation The belief that, in comparison to a reference group, one is getting less than is deserved.

are not met, violence may follow. It is likely, for example, that resentment over U.S. prosperity and global influence plays a role in creating the hatred that leads some people to engage in terrorist attacks against the United States (Plous & Zimbardo, 2004; Pyszczynski, Rothschild, & Abdollahi, 2008).

FOCUS ON **RESEARCH METHODS**

Self-Esteem and the Ultimate Terror

Why is self-esteem so important to so many people? An intriguing answer to this question comes from the *terror management theory* proposed by Jeff Greenberg, Tom Pyszczynski, and Sheldon Solomon. This theory is based on the notion that humans are the only creatures capable of thinking about the future. One result of this ability is the realization that we will all eventually die and the sense of terror it may bring. We can't change this reality, but terror management theory suggests that humans cope with anxiety about death by developing a variety of self-protective psychological strategies, including efforts to establish and maintain high self-esteem (Greenberg, Solomon, & Arndt, 2008; Pyszczynski et al., 2010).

What was the researchers' question?

In one series of experiments, Greenberg and his colleagues (1992) asked whether high self-esteem would in fact serve as a buffer against anxiety—specifically, the anxiety brought on by thoughts about death and pain.

How did the researchers answer the question?

About 150 students at several North American universities participated in these studies, each of which followed a similar format. The first step in each experiment was to manipulate the independent variable—in this case, the participants' self-esteem. To do this, the researchers gave the students feedback on a test they had taken earlier in the semester. Half the participants received esteem-building feedback, such as that their scores indicated high intelligence or a stable personality. The other half received feedback that was neutral (i.e., neither flattering nor unflattering). Next, the students' self-esteem was measured, and these measures showed that the positive feedback actually did produce higher self-esteem than the neutral feedback. In the third phase of each experiment, the researchers manipulated a second independent variable by causing some anxiety in half of the participants in each of the two feedback groups. In one study, anxiety was created by showing some students a film containing pictures of dead people and discussions of death. The others saw a film that did not arouse emotion. In two other experiments, anxiety was created by leading some of the participants to believe (falsely) that they would be receiving a mild electrical shock. Afterward, the participants' anxiety was measured by their self-reports or by monitoring galvanic skin resistance (GSR), an anxiety-related measure of perspiration.

What did the researchers find?

Self-reports or GSR measures revealed that participants in all three experiments were significantly less upset by an anxiety-provoking experience (the death film or the threat of shock) if they had first received esteem-building feedback about their earlier test performance. Other, more recent studies have reported similar findings (Schmeichel et al., 2009).

What do the results mean?

The researchers concluded that these results offer support for terror management theory, and specifically for the notion that self-esteem is important as a buffer against anxiety and other negative feelings. The results may help explain why the maintenance of self-esteem is such a powerful human motive (Leary, 2010). People do not like to feel anxious, and increased self-esteem reduces most people's anxiety.

merican Red Cross
Disaster Relief

USAF/HO/Landov

Protecting Self-Esteem?

According to terror management theory, having high self-esteem protects us from anxiety about death. So when disasters or other events remind people of their mortality, they are likely to raise their self-esteem by engaging in prosocial behavior, such as volunteering or donating blood. Most research on terror management theory has been done in individualist cultures such as North America, where self-esteem is largely based on personal accomplishments. However, the theory has also been supported by preliminary studies in China, Japan, Aboriginal Australia, and other collectivist cultures where feelings of self-worth tend to be more closely tied to membership in family and work groups (Halloran & Kashima, 2004; Heine, Harihara, & Niiya, 2002; Tam, Chiu, & Lau, 2007; Wakimoto, 2006).

What do we still need to know?

Further research by Greenberg and his associates, as well as by others, has provided additional support for terror management theory. For instance, the theory predicts that when people are sensitized to the threat of death, they will seek to protect themselves by suppressing thoughts of death and also by doing things that increase the approval and support of others in the society in which they live. This prediction was borne out by the dramatic increases in volunteering for charity work that were seen following the terrorist attacks of 9/11 (Penner, Brannick, et al., 2005). But not everyone reacts with prosocial behavior when sensitized to the threat of death. The greatest increase in prosocial behavior following reminders about death appears in people who value prosocial behavior (Joireman & Durell, 2007). In other people, those same reminders may be followed by a *reduction* in humanitarian concerns (Hirschberger, 2009). Social psychologists would like to know more about how people's values and personality characteristics are related to the strategies they adopt when dealing with the threat of death.

Researchers also wonder whether terror management theory offers the best explanation of why high self-esteem reduces anxiety. Perhaps people value self-esteem not because it makes them less afraid of death but simply because it is a flattering indicator (a sort of "sociometer") of their acceptance by others (Leary, 2010). According to sociometer theory, people want to have high self-esteem because it tells them that they are liked and accepted. Perhaps the goal of acceptance evolved because people who were excluded from the protective circle of their group were not likely to survive to reproduce. Compared with terror management theory, sociometer theory is certainly a simpler and more plausible explanation of the desire for high self-esteem, but is it the best explanation? Both theories make similar predictions about the effects of self-esteem on anxiety, so it will take additional research to evaluate their relative merits.

Social Identity Theory

TRY THIS

Stop reading for a moment, and fill in the blank in the following sentence: "I am a(n) ____."

Some people complete the sentence by using characteristics such as "hard worker," "good sport," or some other aspect of their *personal* identity. However, many others identify themselves by using a word or phrase that reflects their nationality, gender, or religion (e.g., Lee & Yoo, 2004). These responses reflect **social identity**, our beliefs about the groups to which we belong. Our social identity is thus part of our self-concept (Abrams & Hogg, 2010).

© Bob Daemmrich/The Image Works

All in the Family

Many people find that their place in their family is a central aspect of their social identity. For others, their role in a political, religious, cultural, or business organization may be most vital to that identity. Whatever the specifics, social identity is an important part of people's self-concept, or view of themselves.

social identity The beliefs we hold about the groups to which we belong.

Our social, or group, identity permits us to feel part of a larger whole (Bryant & Cummins, 2010). Its importance is seen in the pride that people feel when a member of their family graduates from college or when a local team wins a big game. In wars between national, ethnic, or religious groups, individuals make sacrifices and even die for the sake of their group identity. A group identity is also one reason people donate money to the needy, support friends in a crisis, and offer other forms of assistance to those with whom they can identify. We will see later, though, that defining ourselves in terms of a group identity can create an "us versus them" mentality that sets the stage for prejudice, discrimination, intergroup conflict, and even terrorism (Abrams & Hogg, 2010).

Social Perception

There is a story about a company president who was having lunch with a man being considered for an executive position. When the man salted his food without first tasting it, the president decided not to hire him. The reason, she explained, was that the company had no room for a person who acted before collecting all relevant information. The candidate lost his chance because of **social perception**, the process through which people interpret information about others, form impressions of them, and draw conclusions about the reasons for their behavior. In this section, we examine how and why social perception influences our thoughts, feelings, and actions.

The Role of Schemas

TRY THIS

In the chapter on perception, we describe a number of Gestalt principles that govern how we organize visual information. For example, what do you see in Figure 17.1? The figure matches what you already know about squares (that they have four equal sides), so your *schema*, or mental representation of this knowledge, probably guided you toward the simplest perception, that it is a square with a notch in it. You could also have described the diagram as a shape formed of eight straight lines, but that would have been far more complicated.

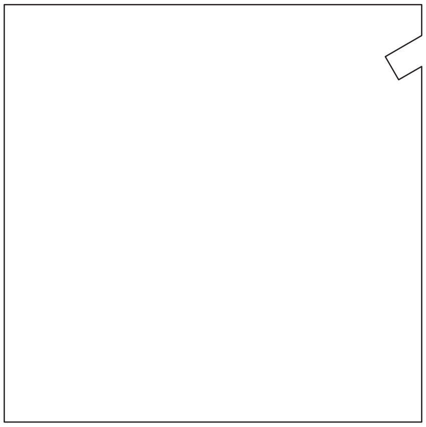

FIGURE 17.1

A Schema-Plus-Correction

TRY THIS Describe this diagram in a single sentence beginning with "This is . . ."; then read our discussion of the figure in the text.

Our perceptions of people follow many of the same laws that govern the perception of objects (Macrae & Quadflieg, 2010). As a result, our prior knowledge, our schemas, about people can have a significant influence on our perceptions of them. First of all, schemas influence what we pay attention to and what we ignore. Characteristics or events that are consistent with our schema about another person usually get more attention than those that are inconsistent with that schema. As a result, we tend to process information about the other person more quickly if it confirms our beliefs about, say, that person's gender or ethnic group than if it violates those beliefs (Smith & Quellar, 2001). Second, schemas influence what we remember about others (Macrae et al., 2002). One classic study demonstrated that if people thought a woman they saw in a video was a waitress, they later recalled that she had a beer with dinner and owned a TV set. If they thought she was a librarian, they remembered that she was wearing glasses and liked classical music (Cohen, 1981). Finally, schemas affect our judgment about other people's behavior. For example, Thomas Hill and his colleagues (1989) found that participants' ratings of male and female friends' sadness were influenced not only by the friends' actual behavior but also by the participants' general schemas about whether men or women experience more sadness.

In other words, through "top-down" processing, schemas can influence—and sometimes bias—person perception in the same way that schemas about objects can affect object perception. And just as schemas help us read sentences in which words have missing letters, they also allow us to "fill in the blanks" about people. So we don't usually ask our doctors or bus drivers to show us their credentials. Our schemas about these people lead us to perceive them as competent, confident, skilled, and experienced. And usually these perceptions are correct. It is only when our expectations are violated that we realize that schemas can lead to errors in our judgment about other people.

social perception The processes through which people interpret information about others, draw inferences about them, and develop mental representations of them.

May I Help You?

TRY THIS Schemas help us categorize people quickly and respond to them appropriately, but schemas can also lead to narrow-mindedness and even prejudice. If this woman does not fulfill your schema—your mental representation—of how carpenters are supposed to look, you might be less likely to ask her advice on your home improvement project. One expert carpenter who manages the hardware department of a large home improvement store told us that most customers walk right past her in order to ask the advice of one of her less experienced male clerks. Are there people you know whose appearance, behavior, or other characteristics don't fit the schemas that most people hold for persons of their age or in their occupation?

First Impressions

The schemas we have about people in general act as lenses that shape our first impressions of others. Those impressions in turn influence both our perceptions of their behaviors and our reactions to those behaviors. First impressions are formed quickly, usually change slowly, and typically have a long-lasting influence. No wonder first impressions are so important in the development of social relations. How do people form impressions of other people? And why are they so resistant to change?

TRY THIS

Forming Impressions Think about your first impression of a close friend. It probably formed rapidly because, as mentioned earlier, existing schemas lead us to infer a great deal about a person on the basis of limited information. One study found that people could make judgments about how trustworthy and competent a person was after seeing that person's face for only a tenth of a second (Willis & Todorov, 2006). Other attributes, such as an ethnic name, may have caused you to draw inferences about your friend's religion, food preferences, or temperament. Clothing or hairstyle may have led you to make assumptions about your friend's political views or taste in music. How many of those assumptions turned out to be true in your friend's case? Perhaps not all of them, but probably quite a few. First impression judgments become much more accurate after as little as one minute of exposure to a new person (Carney, Colvin, & Hall, 2007), and they are not influenced by appearance alone. For example, people are able to make quite accurate judgments about another person's family income and other aspects of socioeconomic status just by watching a "thin slice" of gestures and other nonverbal behavior in a one-minute video of the person in conversation (Kraus & Keltner, 2009).

Noticeable features or actions shape our impressions of others. Those impressions may or may not be correct.

One schema has a particularly strong influence on our first impressions: We tend to assume that people we meet will have attitudes and values similar to our own (Hoyle, 1993; Srivastava, Guglielmo, & Beer, 2010). So all else being equal, we are inclined to like other people. However, it doesn't take much negative information to change our minds. The main reason for this is that most of us don't expect other people to act negatively toward us. When unexpectedly negative behaviors do occur, they capture our attention and lead us to believe that these behaviors reflect something negative about the other person (Taylor, Peplau, & Sears, 2006). For example, we know that there are many reasons why people might be nice to us—because they are kind, because they like our friends, or because they want to sell us a car. But if they do something negative—such as insult us or steal our lecture notes—the most likely explanation is that they are unfriendly or have other undesirable personality traits. In other words, negative behavior carries more weight than positive behavior in shaping first impressions (Lount et al., 2008).

Lasting Impressions Does your friend seem the same today as when you first met? First impressions can change, but the process is usually slow. One reason is that negative first impressions may cause us to avoid certain people, thus reducing our exposure to new information that might change our view of them (Denrell, 2005). Further, most people want to keep their social environment simple and easy to understand (Kenrick, Neuberg, & Cialdini, 2010). We cling to our beliefs about the world, often using our schemas to preserve a reality that fits our expectations. Holding on to existing impressions appears to be part of this effort. If your friend has recently said or done something that violates your expectations, your view of her probably did not change much, if at all. In fact, you may have acted to preserve your impression by thinking something like, "She's just not herself today." In other words, impressions are slow to change because the meaning we give to new information about people is shaped by what we already know or believe about them (Kenrick, Neuberg, & Cialdini, 2010).

Self-Fulfilling Prophecies Another reason first impressions tend to be stable is that we often do things that cause others to confirm our impressions (Madon et al., 2004). If teachers expect particular students to do poorly in mathematics, those students may sense this expectation, exert less effort, and perform below their ability level. Similarly, if mothers expect their young children to eventually abuse alcohol, those children are more likely to do so than the children of mothers who didn't convey that expectation (Madon et al., 2006). When, without our awareness, schemas cause us to

Self-Fulfilling Prophecies in the Classroom

If teachers inadvertently spend less time helping children who impressed them as "dull," those children may not learn as much, thus fulfilling the teachers' expectations. If the girl at the far right has not impressed her teacher as being bright, how likely do you think it is that she will be called on?

subtly lead people to behave in line with our expectations, a **self-fulfilling prophecy** is at work. In one experiment on self-fulfilling prophecies, some people were led to believe that a person they were about to meet would be friendly and accepting; others were led to believe that the person would reject them. Those who expected acceptance behaved in a much warmer, friendlier way, which made it much more likely that their new acquaintance actually *did* accept them (Stinson et al., 2009).

Self-fulfilling prophecies also help maintain judgments about groups. If you assume that members of a certain ethnic group are unfriendly, for example, you might be defensive or even hostile when you meet a member of that group. If the person reacts to your behavior with hostility, your prophesy would be fulfilled, and you would have an even stronger impression that "all those people" are unfriendly (Kenrick, Neuberg, & Cialdini, 2010).

Explaining Behavior: Attribution

So far, we have considered how people form impressions about the characteristics of other people. But our perceptions of others include another key element: explanations of their behavior. People tend to form *implicit theories* about why people (including themselves) behave as they do and about what behavior to expect in the future. Psychologists use the term **attribution** to describe the process we go through to explain the causes of behavior (including our own).

Suppose that a classmate fails to return some borrowed notes on time. You could attribute this behavior to many causes, from an unavoidable emergency to simple selfishness. Which of these alternatives you choose is important because it will help you *understand* your classmate's behavior, *predict* what will happen if this person asks to borrow something in the future, and decide how to *control* the situation should it arise again. Similarly, your decision to stick with a troubled relationship or end it may be influenced by whether you attribute your partner's recent indifference to stressful circumstances or a loss of love.

People tend to attribute behavior in a particular situation to either internal causes (characteristics of the person) or external causes (characteristics of the situation). If you thought your classmate's failure to return your notes was due to lack of consideration or laziness, you would be making an *internal attribution.* If you thought that the oversight was caused by time pressure or a family crisis, you would be making an *external attribution.* And if you failed an exam, you could explain it by concluding either that you're not very smart (internal attribution) or that your job or family responsibilities didn't leave you enough time to study (external attribution). The attribution that you make may in turn determine how much you study for the next exam or even whether you decide to stay in school.

Sources of Attributions Harold Kelley (1973) proposed an influential theory of how people (whom Kelley called *observers*) make attributions about the actions of other people (whom Kelley called *actors*). To illustrate this theory, suppose that you are at your parents' house for the weekend. You want to invite your friend Ralph to come for dinner, but your father says no. According to Kelley, understanding the reasons for your father's behavior requires information about three key variables: consensus, consistency, and distinctiveness:

1. *Consensus* is the degree to which other people's behavior is similar to that of the actor—in this case, your father. If everyone you know avoids Ralph, your father's behavior has a high degree of consensus, and you would attribute his reaction to an external cause (probably something about Ralph). However, if everyone except your father likes Ralph, your father's negative response would have low consensus. In that case, you would probably attribute the response to something about your father, such as rudeness or having a personal dislike for Ralph.
2. *Consistency* is the degree to which the behavior is the same across time or situations. If your father has invited Ralph to dinner several times in the past but rejects him this time, the consistency of his behavior is low. Low consistency

self-fulfilling prophecy A process through which our expectations about another person cause us to act in ways that lead the person to behave as we expected.

attribution The process of explaining the causes of people's behavior, including our own.

suggests that your father's behavior is attributable to external causes, such as conflicts at work that have left your father feeling unsociable. If your father's behavior toward Ralph is always hostile, it has high consistency. But is your father's consistent behavior attributable to an internal cause (his consistent rudeness) or to an external cause (consistent conflicts at work)? This question is difficult to answer without information about distinctiveness.

3. *Distinctiveness* concerns the extent to which the actor's response to one situation stands out from responses to similar situations. If your father is nasty to all your friends, his behavior toward Ralph has low distinctiveness. Behavior that is low in distinctiveness is usually attributable to internal causes, such as personality traits. However, if your dad gets along with everyone except Ralph, his behavior has high distinctiveness, and your attribution about the cause of his behavior is likely to shift toward a cause other than your father's personality, such as how Ralph acts.

In summary, Kelley's theory suggests that people are most likely to make internal attributions about an actor's behavior when there is low consensus, high consistency, and low distinctiveness. If you observe your boss insulting customers (a situation of low consensus, inasmuch as most people in business are polite to customers) every day (high consistency) no matter who the customers are (low distinctiveness), you would probably attribute this behavior to the boss's personality rather than to the customers' unreasonable demands or some other external cause. But if you saw the boss on just one day (low consistency) being rude (low consensus) to one particular customer (high distinctiveness), you would probably attribute the incident to the customer's behavior, an external factor.

Culture and Attribution Most theories of causal attribution were developed by North American psychologists who assumed that people all over the world use the same kinds of information to make similar kinds of attributions. However, there is substantial evidence to suggest that this may not be true (Nisbett & Masuda, 2006; Savani et al., 2010). For example, when people in the United States are asked to explain why someone has acted in a certain way, they are more likely than people from many other cultures to make internal attributions. That is, they tend to attribute the person's behavior to personality characteristics such as greed or generosity rather than to external, situational factors such as unemployment or a sudden inheritance. Attributional tendencies can even differ between subgroups within the same culture. In one study, U.S. college students from working-class backgrounds were more likely than those from middle-class backgrounds to use internal attributions when explaining the

Why Are They Helping?

Helping occurs all around the world, but research shows that people's attributions, or explanations, about why it happens can differ from culture to culture.

behavior of another person (Bowman, Kitayama & Nisbett, 2009). Cross-cultural differences in attribution and other aspects of social cognition may explain why people in different cultures and even different subcultures sometimes have so much difficulty understanding one another.

Errors in Attribution

Whatever their background, most people are usually logical in their attempts to explain behavior (Kenrick, Neuberg, & Cialdini, 2010). However, they are also sometimes prone to *attributional errors* that can distort their views of behavior (Baumeister & Bushman, 2008).

The Fundamental Attribution Error

North American psychologists have paid special attention to the **fundamental attribution error**, a tendency to overattribute the behavior of others to internal factors, such as personality traits (Fiske & Taylor, 2008). Imagine that you hear a student give an incorrect answer in class. You will probably attribute this behavior to an internal cause and assume that the person is not very smart. In doing so, however, you might be failing to consider the possible influence of various external causes, such as lack of study time.

A related form of cognitive bias is called the *ultimate attribution error.* When members of a social or ethnic **outgroup** (people we see as "different") do something positive, we attribute their behavior to luck or some other external cause. But we attribute their negative behavior to an internal cause, such as dishonesty (Pettigrew, 1979). At the same time, when members of an **ingroup** (people we see as being like ourselves) do good deeds, we attribute the behavior to integrity or other internal factors. If they do something bad, we attribute it to some external cause. Because of the ultimate attribution error, members of the outgroup receive little credit for their positive actions, and members of the ingroup get little blame for their negative actions (Khan & Liu, 2008). Biases such as the ultimate attribution error help maintain people's negative views of outgroups and positive views of their own ingroup (Fiske, 1998).

Attributional Bias

Men whose thinking is colored by the ultimate attribution error might assume that women who succeed at tasks associated with traditional male roles are just lucky but that men succeed at those tasks because of their skill (Deaux & LaFrance, 1998). When this attributional bias is in operation, people who are perceived as belonging to an outgroup, whether on the basis of their sex, age, sexual orientation, religion, ethnicity, or other characteristics, may be denied fair evaluations and equal opportunities.

Like other aspects of social cognition, the fundamental attribution error may not be universal (Miyamoto & Kitayama, 2002). Researchers have found, for example, that people in collectivist cultures such as India, China, Japan, and Korea are less likely than those in the individualist cultures of North America and Europe to attribute people's behavior to internal causes. Instead, these people tend to see behavior as due less to individual characteristics and more to the situations or contexts in which the person is immersed (Heine & Buchtel, 2009).

Researchers have also pointed out that attributing behavior to internal causes may not always be an error. Sometimes an internal attribution may simply be the most reasonable attribution to make, given the information available (Sabini, Siepmann, & Stein, 2001). Further, David Funder has argued that in many situations, personality characteristics and other internal factors are indeed the true causes of behavior (Funder & Fast, 2010). In other words, according to Funder, social perception is much more accurate than many psychologists have previously recognized.

Other Attributional Errors

The inclination toward internal attributions is much less pronounced when people explain their own behavior. In fact, people tend to show the **actor-observer effect**. Whereas people often attribute other people's behavior to internal causes, they tend to attribute their own behavior to external factors, especially when the behavior is inappropriate or inadequate. For example, when Australian students were asked why they sometimes drive too fast, they focused on circumstances such as being late but saw other people's dangerous driving as a sign of aggressiveness or immaturity (Harré, Brandt, & Houkamau, 2004). Similarly, when you drive slowly, it's because you are looking for an address or for some other good reason, not because you're a dimwitted loser like that jerk who crawled along in front of you yesterday.

fundamental attribution error A bias toward overattributing the behavior of others to internal causes.

outgroup Those whom we perceive as being different from ourselves.

ingroup Those whom we perceive as being similar to ourselves.

actor-observer effect The tendency to attribute other people's behavior to internal causes while attributing our own behavior (especially errors and failures) to external causes.

The actor-observer effect occurs mainly because people have different kinds of information about their own behavior and about the behavior of others. When *you* are acting in a situation—giving a speech, perhaps—the information that is most available to you is likely to be external and situational, such as the temperature of the room and the size of the audience. You also have a lot of information about other external factors, such as the amount of time you had to prepare your talk or the upsetting argument that occurred this morning. If your speech is disorganized and boring, you can easily attribute it to one or all of these external causes. But when you observe someone else, the most noticeable stimulus in the situation is *that person*. You do not know what happened to the person last night or this morning, so you are likely to attribute whatever he or she does to enduring internal characteristics (Moskowitz, 2005).

Of course, people do not always attribute their own behavior to external forces. In fact, the degree to which they do so depends on whether the outcome of their behavior is positive or negative. In one study, when people were asked what they saw as the cause of their good and bad experiences when shopping online, they tended to take personal credit for positive outcomes but to blame the computer for the negative ones (Moon, 2003). In other words, these people showed a **self-serving bias**, the tendency to take personal credit for success but to blame external causes for failure. This tendency has been found in almost all cultures, but as with the fundamental attribution error, it is usually more pronounced among people from individualist Western cultures than among those from collectivist Eastern cultures (Mezulis et al., 2004).

The Self-Protective Functions of Social Cognition

The self-serving bias occurs partly because, as we mentioned earlier, people are motivated to maintain their self-esteem—and ignoring negative information is one way to do so. If you just failed an exam, it is painful to admit that your grade was fair, so you might blame your performance on an unreasonably demanding instructor. Other forms of social cognition also help people think about their failures and shortcomings in ways that protect their self-esteem (Shepperd, Malone, & Sweeny, 2008).

One example is *unrealistic optimism,* the tendency to believe that positive events (such as financial success or having a gifted child) are more likely to happen to yourself than to others and that negative events (such as being in an accident or having cancer) are more likely to happen to others than to yourself (Lin & Raghubir, 2005). This self-protective bias can reduce anxiety and blunt the impact of stress for a while. Notice, though, that we are not referring to the optimistic (but realistic) perspective on life that is associated with good physical and mental health (see the chapter on health, stress, and coping). Quite the opposite. *Unrealistic* optimism tends to persist even when there is strong evidence against it and can lead people to engage in potentially harmful behaviors. Unrealistically optimistic smokers underestimate their chances of getting lung cancer and are also less likely than others to believe that smoking causes lung cancer or that quitting can lower their risk (Dillard, McCaul, & Klein, 2006). Similarly, college students who are unrealistically optimistic about the risks of excessive drinking are more likely to have alcohol-related problems than those who hold more realistic views (Dillard, Midboe, & Klein, 2009). And many injuries and deaths are suffered each year by people who felt sure that they were immune to the dangers of driving after drinking or riding a motorcycle without a helmet.

Like the defense mechanisms described in the personality chapter, self-protective cognitive biases can help us temporarily escape from unpleasant thoughts and feelings. But as in the case of unrealistic optimism, these biases also set the stage for a somewhat distorted view of reality and can cause problems in the long run. ("In Review: Some Biases in Social Perception" summarizes our discussion of these biases).

self-serving bias The tendency to attribute our successes to internal characteristics while blaming our failures on external causes.

IN REVIEW Some Biases in Social Perception

Bias	Description
Importance of first impression	Ambiguous information is interpreted in line with a first impression, and the initial schema is recalled better and more vividly than any later correction to it. Actions based on this impression may elicit behavior that confirms it.
Fundamental attribution error	The tendency to attribute the behavior of others to internal factors.
Actor-observer effect	The tendency to attribute our own behavior to external causes while attributing the behavior of others to internal factors.
Self-serving bias	The tendency to attribute one's successes to internal factors and one's failures to external factors.
Unrealistic optimism	The tendency of people to believe that good things will happen to them but that bad things will not.

1. The fundamental attribution error appears to be somewhat less likely to occur among people in ____________ cultures.

2. First impressions form ____________ but change ____________.

3. If you believed that immigrants' successes are due to government help but that their failures are due to laziness, you would be committing the ____________ error.

Attitudes

People's views about health or safety reflect their *attitudes,* an aspect of social cognition that social psychologists have studied longer and more intensely than any other. An **attitude** is the tendency to think, feel, or act positively or negatively toward objects in our environment (Banaji & Heiphetz, 2010). Attitudes play an important role in guiding how we act toward other people, what political causes we support, which products we buy, and countless other daily decisions.

The Structure of Attitudes

Social psychologists have long viewed attitudes as having three components (Banaji & Heiphetz, 2010). The *cognitive* component is a set of beliefs about the attitude object. The emotional, or *affective,* component includes feelings about the object. The *behavioral* component is the way people act toward the object. If these components were always in harmony, we would be able to predict people's behavior toward the homeless, for example, on the basis of the thoughts or feelings they express. This is often not the case, however (Bohner & Schwarz, 2001). Many people's positive thoughts and supportive emotions regarding homeless people are never translated into actions aimed at helping them.

What determines whether people's behavior will be consistent with the cognitive and affective components of their attitudes? Several factors are important. For one thing, behavior is more likely to be consistent with attitude when people see the attitude as important and relevant to their lives (Kenrick, Neuberg, & Cialdini, 2010). Second, consistency is more likely when the behavioral component of the attitude is in line with a *subjective norm,* our view of how important people in our lives want us to act. Conflict between attitudes and subjective norms may cause us to behave in ways that are inconsistent with our attitudes (Ajzen & Gilbert-Cote, 2008). For example, someone who believes that the rights of gay men and lesbians should be protected might not campaign for this cause because doing so would upset family members or friends who are against it. Third, attitude-consistent behavior is more likely when people have *perceived control,* the belief that they can actually perform such behavior (Fishbein & Ajzen, 2010). The cognitive and

attitude A predisposition toward a particular cognitive, emotional, or behavioral reaction to objects.

A Reminder About Poverty

TRY THIS Photographs such as this one are used by fundraising organizations to remind us of the kind thoughts and charitable feelings we have toward needy people and other social causes. As a result, we may be more likely to behave in accordance with the cognitive and affective components of our attitudes and make a donation to these causes. Browse through some newspapers, magazines, and Web sites, and calculate the percentage of such photos you find in ads for charitable organizations.

© thefinalmiracle/Shutterstock

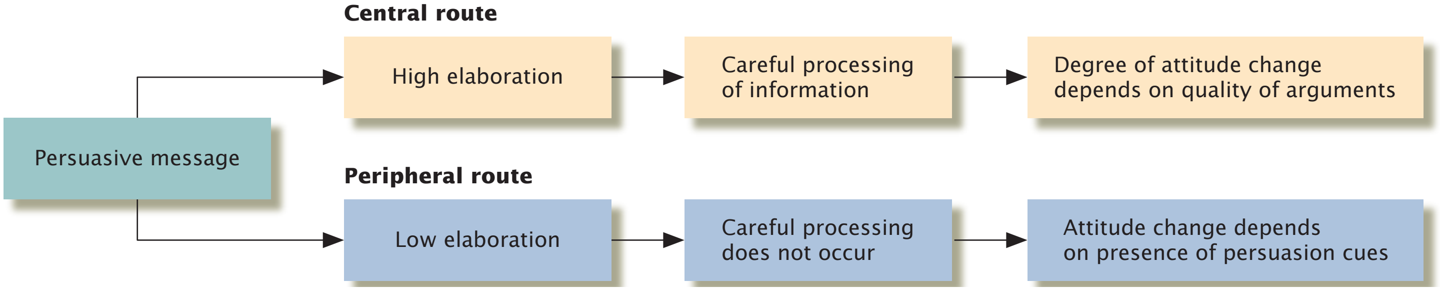
affective components of your attitude about the homeless may be positive, but if you don't believe you can do anything about homelessness, you are not likely to even try. Fourth, *direct experience* with the attitude object increases the likelihood of attitude-consistent behavior (Glasman & Albarracín, 2006). This is because attitudes based on direct experiences are more stable and memorable and thus more likely to come into play when the attitude object is present. Accordingly, you might be more likely to actively support and perhaps even participate in efforts to help the homeless if you have come to know a homeless person on your campus than if you have only read about their plight.

The importance of direct experience in creating consistency among attitude components reflects the cognitive network theories described in the chapters on learning and memory. According to these theories, attitudes are stored in long-term memory as networks of cognitions—interconnected evaluations and beliefs about attitude objects (Yan & Tourangeau, 2007). When you encounter an attitude object, the cognitions associated with it in your cognitive network are activated. If your thoughts and feelings are well defined and come easily to mind, your behavior is likely to be consistent with them. If not, there may be less consistency (Glasman & Albarracín, 2006).

Forming Attitudes

People are not born with specific attitudes toward specific objects, but their attitudes about new objects begin to appear in early childhood and continue to emerge throughout life. How do attitudes form? Some of the variation we see in people's attitudes may reflect genetic influences inherited from their parents (Albarricín & Vargas, 2010), but what they *learn* from their parents and others appears to play the major role in attitude formation. In childhood, modeling and other forms of social learning are especially important. Children learn not only the names of objects but also what to believe and feel about them and how to act toward them. For example, a parent may teach a child not only that snakes are reptiles but also that they should be feared and avoided. So as children learn concepts such as "reptile" or "work," they learn attitudes about those concepts, too.

Attitudes can also be influenced by classical and operant conditioning. In one study demonstrating this process, certain cartoon characters were associated with positive words (e.g., *excellent*) and images (e.g., an ice-cream sundae) and others were associated with negative words and images (Olson & Fazio, 2001). Afterward, participants in this study liked the characters associated with the positive stimuli much more than those associated with the negative ones. No wonder so many advertisers present



Central route
Persuasive message
High elaboration
Careful processing of information
Degree of attitude change depends on quality of arguments
Peripheral route
Low elaboration
Careful processing does not occur
Attitude change depends on presence of persuasion cues

FIGURE 17.2

The Elaboration Likelihood Model of Attitude Change

TRY THIS The central route to attitude change involves carefully processing and evaluating the content of a message (high elaboration). The peripheral route involves low elaboration, or processing, of the message and relying on persuasion cues such as the attractiveness of the person making the argument (Cacioppo, Petty, & Crites, 1993). Jot down two examples of TV commercials that attempt to activate the central route and two others that try to activate the peripheral route. Which kind was easier to bring to mind? If it was the latter, what does that say about how advertisers hope to persuade you to buy their products?

enjoyable music or attractive images in association with the products they are trying to sell (Walther & Langer, 2008). As for operant conditioning, parents, teachers, and peers actively shape children's attitudes by rewarding the children for stating particular views. The *mere-exposure effect* is influential as well: All else being equal, attitudes toward an object will become more positive the more frequently people are exposed to it (Winkielman & Cacioppo, 2004). The mere-exposure effect helps explain why we sometimes come to like a song only after hearing it several times—and why we may come to like products and candidates only after being repeatedly exposed to commercials and political ads. One study showed, for example, that European American college students showed an increased liking for photos of Asian Americans and African Americans after previously seeing many photos of people from these groups (Zebrowitz, White, & Wieneke, 2008).

Changing Attitudes

TRY THIS

Although mere exposure can help to form new attitudes, it is not very effective at changing existing ones (Crano & Prislin, 2006). If you are already strongly against requiring motorcyclists to wear helmets, for example, that attitude is unlikely to change much no matter how often you see riders wearing helmets. Changing attitudes usually requires more active efforts, mainly in the form of persuasive messages. The nearly $100 billion a year spent on advertising in the United States alone provides just one example of how people are constantly trying to change our attitudes. Stop for a moment and make a list of other examples, perhaps starting with the messages of groups concerned with abortion or recycling—and don't forget your friends who want you to think the way they do.

Two Routes to Attitude Change Whether a persuasive message succeeds in changing attitudes depends primarily on three factors: (1) the person communicating the message, (2) the content of the message, and (3) the audience who receives it (Albarracín & Vargas, 2010). The **elaboration likelihood model** of attitude change provides a framework for understanding when and how these factors affect attitudes (Petty & Briñol, 2008). As shown in Figure 17.2, the model is based on the notion that persuasive messages can change people's attitudes through one of two main routes.

The first is called the *peripheral route* because when it is activated, we devote little attention to the central content of the persuasive message. Instead, we tend to be affected by the *persuasion cues* that surround it, such as the confidence, attractiveness, or other characteristics of the person delivering the message. Persuasion cues influence attitude change even though they say nothing about the logic or validity of the message content. Commercials in which movie stars or other attractive nonexperts praise pain relievers or hearing aids or political candidates are designed to operate via the peripheral route to attitude change.

By contrast, when the *central route* to attitude change is activated, the content of the message becomes more important than the characteristics of the communicator in determining attitude change. A person following the central route uses logical steps—such as those outlined in the Thinking Critically sections of this book—to rationally analyze the content of the persuasive message. This analysis considers the

elaboration likelihood model A model suggesting that attitude change can be driven by evaluation of the content of a persuasive message (central route) or by irrelevant persuasion cues (peripheral route).

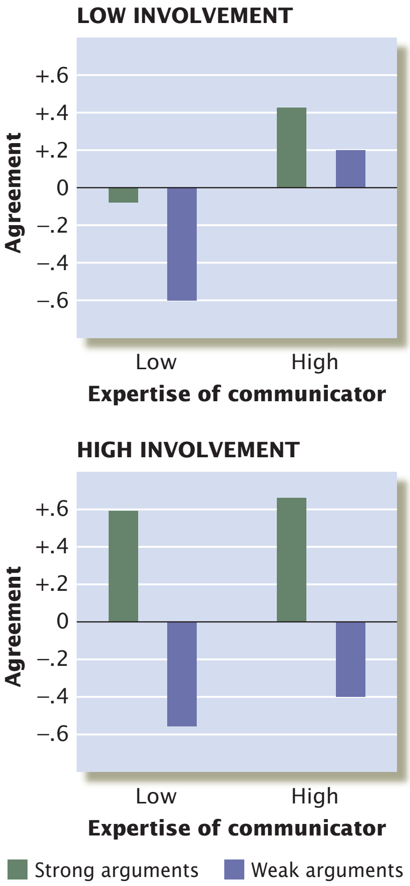


FIGURE 17.3

Personal Involvement and Routes to Attitude Change

In the study represented here, students' reactions to messages supporting exit exams for seniors depended on whether they thought the policy would begin immediately (high involvement) or only after they had graduated (low involvement). In the low-involvement condition, students followed a peripheral route to attitude change, agreeing with messages from expert communicators regardless of how logical they were. More involved students followed a central route, changing their minds only if the message contained a strong, logical argument.

Sources: Data from Petty, Cacioppo, & Goldman (1981); Petty, Cacioppo, & Schumann (1983).

validity of the message's claims, determines whether the message leaves out important information, assesses alternative interpretations of evidence, and so on.

What determines which route people will follow? Personal involvement with the content of the message is one important factor. The elaboration likelihood model proposes that the more personally involving a topic is, the more likely it is that the central route will be activated (Bohner, Erb, & Siebler, 2008). Suppose, for example, that you heard someone arguing for the elimination of student loans in Brazil. This message might persuade you via the peripheral route if it came from someone who looked attractive and sounded intelligent. However, you would be more likely to follow the central route if the message proposed doing away with student loans at your own school. You might be persuaded, but only if the logic of the message was undeniable (see Figure 17.3). This is why celebrity endorsements tend to be most effective when the products being advertised are relatively unimportant to the audience.

"Cognitive busyness" is another factor affecting which attitude change route is activated. If you are busy thinking about other things while a message is being delivered, you will be unable to pay much attention to its content. In this case, activation of the peripheral route becomes more likely. Attitude change processes are also related to personality characteristics. For example, people with a strong *need for cognition* like to engage in thoughtful mental activities and are therefore more likely to use the central route to attitude change (Suedfeld & Tetlock, 2001). In contrast, people whose discomfort with uncertainty creates a *need for closure* are more likely to use the peripheral route (Cacioppo et al., 1996).

Persuasive messages are not the only means of changing attitudes. Another approach is to get people to act in ways that are inconsistent with their current attitudes in the hope that they will adjust those attitudes to match their behavior. Often such adjustments do occur. Cognitive dissonance theory and self-perception theory each attempt to explain why.

Cognitive Dissonance Theory Leon Festinger's classic **cognitive dissonance theory** holds that people want their thoughts, beliefs, and attitudes to be consistent with one another and with their behavior. When people experience inconsistency, or *dissonance*, among these elements, they become anxious and are motivated to make them more consistent (Elliot & Devine, 1994; Festinger, 1957; Olson & Stone, 2005). For example, someone who believes that "smoking is unhealthy" but must also acknowledge that "I smoke" would be motivated to reduce the resulting dissonance. Because it is often difficult to change behavior, people usually reduce cognitive dissonance by changing inconsistent attitudes. So rather than quit smoking, the smoker might decide that smoking is not so dangerous.

In one of the first studies of cognitive dissonance, Festinger and his colleague Merrill Carlsmith (1959) asked people to turn pegs in a board, a very dull task. Later, some of these people were asked to persuade a person waiting to participate in the study that the task was "exciting and fun." Some were told that they would be paid $1 to tell this lie; others were promised $20. After they had talked to the waiting person, their attitudes toward the dull task were measured.

Figure 17.4 shows the surprising results. The people who were paid just $1 to lie liked the dull task more than those who were paid $20. Why? Festinger and Carlsmith argued that telling another person that a boring task is enjoyable will produce dissonance (between the thoughts "I think the task is boring" and "I am saying it is fun"). To reduce this dissonance, the people who were paid just $1 adopted a favorable attitude toward the task, making their cognitions consistent: "I think the task is fun" and "I am saying it is fun." But if a person has adequate justification for telling a lie, any dissonance that exists will be reduced simply by thinking about the justification. The participants who were paid $20 thought they had adequate justification for lying and so did not need to change their attitudes toward the task.

Hundreds of other experiments have also found that when people publicly engage in behaviors that are inconsistent with their privately held attitudes, they are likely to change their attitudes to be consistent with their behavior (Cooper, Mirabile, & Scher, 2005). These experiments have also found that behavior-attitude inconsistency

cognitive dissonance theory A theory asserting that attitude change is driven by efforts to reduce tension caused by inconsistencies between attitudes and behaviors.

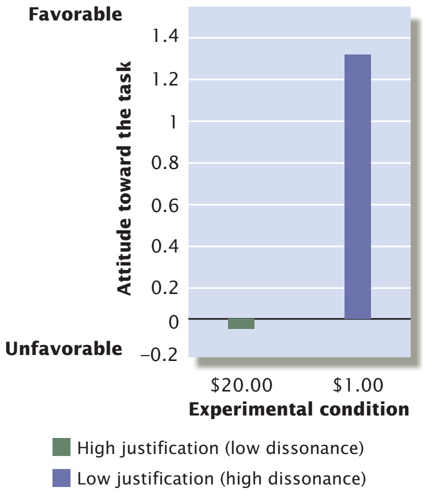

FIGURE 17.4

Cognitive Dissonance and Attitude Change

According to cognitive dissonance theory, the $20 people were paid to say that a boring task was enjoyable provided them with a clear justification for lying. Having been paid to lie, they should experience little dissonance between what they said and what they thought about the task. And in fact their attitude toward the task was not positive. However, people who received only $1 had little justification to lie and reduced their dissonance mainly by displaying a more positive attitude toward the task.

will produce attitude change when (1) the inconsistency causes some distress or discomfort and (2) changing attitudes will reduce this distress or discomfort. But what causes the discomfort in the first place? There is considerable debate among attitude researchers about this question (Harmon-Jones, Amodio & Harmon-Jones, 2009).

One possible answer is that discomfort results when people's positive self-concept (e.g. "I am honest") is threatened by the recognition that they have done something inconsistent with that self-concept. For example, if they have encouraged another person to do something that they themselves didn't believe in or that they themselves wouldn't do, this inconsistency makes most people feel uncomfortable, so they change their attitudes to reduce or eliminate such feelings (Stone & Fernandez, 2008). If people can persuade themselves that they really believed in what they did, the perceived inconsistency disappears, and their positive self-concepts are restored. Changing one's private attitude to match one's public actions is one way to accomplish this self-persuasion. Claude Steele's work on *self-affirmation* supports this explanation of why dissonance causes discomfort (e.g., Steele, Spencer, & Lynch, 1993). He has found that people will not change their attitudes after recognizing their own attitude-behavior inconsistency if they can do something else that makes them look good and feel good about themselves—such as showing how smart or competent they are. In other words, when people do not need to change their attitudes to reestablish a positive view of themselves, they don't.

The circumstances that lead to cognitive dissonance may be different in the individualist cultures of Europe and North America than in collectivist cultures such as Japan and China. In individualist cultures, dissonance typically arises from behaving in a manner inconsistent with one's own beliefs, because this behavior causes self-doubt. But in collectivist cultures, dissonance typically arises when such behavior causes the person to worry about one's reputation with others (Kitayama et al., 2004). Cultural values also operate in shaping dissonance-reducing strategies. For example, people from individualist cultures can reduce the unpleasant feelings that accompany dissonance by affirming their value as unique individuals, whereas people from collectivist cultures can reduce the same kinds of feelings by affirming the value of the groups to which they belong (Hoshino-Browne et al., 2005).

Self-Perception Theory Over the years, cognitive dissonance theory has been challenged by other explanations of why attitudes change when they are inconsistent with behavior (Dunning, 2001). The first and strongest of these challenges came from Daryl Bem's **self-perception theory**. Unlike dissonance theory, self-perception theory does not assume that people experience discomfort when their attitudes are inconsistent with their behaviors. According to Bem (1967), situations often arise in which people are not quite sure about their attitudes. When this happens, Bem says, people look at their own behavior under particular circumstances and then infer what their attitude must be. The person says, "If I did that under those circumstances, my attitude must be this." This process makes their attitudes consistent with their behavior, but the process is not driven by tension or discomfort.

Self-perception explanations of attitude change seem reasonable, but two kinds of evidence are inconsistent with it. First, brain-imaging studies have found that specific patterns of brain activity are associated with the experience of cognitive dissonance and that the appearance of these patterns strongly predicts the appearance of attitude change (van Veen et al., 2009). These findings—combined with earlier evidence that people become physiologically aroused and feel uncomfortable when their attitudes and behavior are inconsistent (Elliot & Devine, 1994)—suggest that some kind of internal tension is, in fact, created by cognitive dissonance. Second, people adjust their attitudes to match their behavior even when they are unable to reflect on that behavior—a process that is crucial to self-perception theory. In one experiment, for example, researchers studied the effects of attitude-behavior inconsistencies in people suffering from anterograde amnesia, a condition described in the memory chapter that leaves people unable to recall what they have said or done minutes earlier. Like the participants in other attitude change experiments, these people, too, changed their attitudes to be more consistent with their behavior (Lieberman et al., 2001).

self-perception theory A theory suggesting that attitudes can change as people consider their behavior in certain situations and then infer what their attitude must be.

IN REVIEW Forming and Changing Attitudes

Type of Influence	Description
Social learning and conditioning	Attitudes are usually formed through observation of how others behave and speak about an attitude object, as well as through classical and operant conditioning.
Elaboration likelihood model	People change attitudes through either a central or a peripheral route, depending on factors such as personal involvement, "cognitive busyness," and personality characteristics.
Cognitive dissonance and self-perception	Inconsistencies between attitudes and behaviors can produce attitude change, as can reviewing one's behavior in light of circumstances.

1. **According to the elaboration likelihood model, people are more likely to pay close attention to the content and logic of a persuasive message if the ____________ route to attitude change has been activated.**
2. **Holding attitudes that are similar to those of your friends illustrates the importance of ____________ in attitude formation.**
3. **According to cognitive dissonance theory, we tend to reduce conflict between attitudes and behaviors by changing our ____________.**

Although these results do not support self-perception theory, they do not entirely invalidate it. It may be that self-perception theory applies best either when people have no prior attitude toward some object or when the discrepancy between their attitude and their behavior is slight. For instance, if you know you prefer Coca-Cola but you also know that you just drank a Pepsi, this self-perception may drive an attitude change toward Pepsi even though you did not experience much dissonance. However, when attitudes are strong and clearly defined and the inconsistency between attitudes and behaviors is larger and more important to a person's self-concept, attitude change appears to occur mainly because of cognitive dissonance (Dunning, 2001). ("In Review: Forming and Changing Attitudes" summarizes some of the major processes through which attitudes are formed and changed.)

LINKAGES

Biological and Social Psychology

LINKAGES What happens in the brains of prejudiced people? (a link to Biological Aspects of Psychology, p. 76)

Social psychologists' research on thoughts, feelings, and behaviors was once entirely separate from research on the biological processes that underlie those thoughts, feelings, and behaviors (Cacioppo & Berntson, 2005). In fact, social psychologists believed that it was not possible to reduce complex social psychological processes to the firing of neurons or the secretion of hormones. At the same time, biological psychologists, more commonly known as *neuroscientists,* viewed the study of social psychology as having little, if any, relevance to the understanding of behavioral genetics or the functioning of the nervous, endocrine, or immune systems. Recently, however, scientists in both subfields have begun to take a closer look at each other's research and how their subfields are related. The result has been the emergence of a new specialty called *social neuroscience* or *social cognitive neuroscience* (Lieberman, 2010). This new specialty focuses on the neurological aspects of social processes and is part of a more general trend toward research on the interaction of biological and social processes.

There are already many reasons to believe that this research approach will be valuable. For example, the chapter on health, stress, and coping contains numerous examples of how social stressors can have health-related biological consequences. Health psychologists have also found that the quality of a person's social relationships can affect biological processes ranging from the functioning of the immune system to the healing of wounds (Gouin et al., 2008, 2010; Kiecolt-Glaser, 2009). The social environment can affect even the way genes express themselves (Cole, 2009). In one study, for example, monkeys were selectively bred to react strongly to even mild stressors. These animals' oversensitivity appeared to be based on a specific gene, but researchers found it possible to modify the effects of this gene by changing the monkeys' social situation. When the animals were paired with a warm, nurturant foster mother, their oversensitivity diminished significantly, and it remained low even when they were later separated from her (Suomi, 1999).

Researchers are also beginning to identify biological processes associated with many social processes. We have already mentioned studies that measured activity in the brain and the autonomic nervous system during cognitive dissonance. Other examples can be seen in research on the emotion-related brain activity that accompanies the ethnic prejudice and stereotyping that we discuss in the next section (Amodio & Lieberman, 2009). Using functional magnetic resonance imaging technology, some researchers have found that European Americans who were prejudiced against African Americans showed significantly more amygdala activity when looking at pictures of black people than when looking at pictures of white people (Hart et al., 2000; Phelps et al., 2000). Researchers have also used fMRI to study people's emotional reactions to other people's distress (Lamm, Batson, & Decety, 2007). They found patterns of brain activity that were quite different depending on whether the individual experienced empathy for a distressed person or simply observed the person's distress. Studies such as this one are shedding some light on the biological aspects of empathy, and they may eventually lead to a broader understanding of the factors influencing people's motivation to help each other (Decety, 2011; see the chapter on social influence). Social neuroscientists have also used electroencephalography (EEG) and other techniques to record the brain activity associated with positive and negative attitudes about people and objects (e.g., Amodio et al., 2004). Their research has shown that these evaluative reactions are associated with activity in specific brain regions (Cacioppo, Crites, & Gardner, 1996).

Social neuroscience is still in its infancy, but this new field of research already shows great promise for improving our understanding of the linkages among social, cognitive, and biological phenomena, as well as of complex social and physiological processes (Lieberman, 2010).

Prejudice and Stereotypes

All of the principles that underlie impression formation, attribution, and attitudes come together to create prejudice and stereotypes. **Stereotypes** are the perceptions, beliefs, and expectations a person has about members of some group. They are schemas about entire groups of people (Dovidio & Gaertner, 2010). Usually, stereotypes involve the false assumption that all members of a group share the same characteristics. The characteristics that make up the stereotype may be positive, but they are usually negative. The most common and most powerful stereotypes focus on observable personal attributes, particularly ethnicity, gender, and age (Operario & Fiske, 2001).

The stereotypes people hold can be so ingrained that their effects on behavior can be automatic and unconscious (Dovidio et al., 2009). In one study, for example, European American and African American participants played a video game in which white or black men suddenly appeared on a screen holding objects that might be weapons (Correll et al., 2002; see Figure 17.5). The participants were instructed to immediately "shoot" an armed man but not an unarmed one. Under this time pressure, the participants' errors were not random. If they "shot" an unarmed man, he was significantly more likely to be black than white. If they failed to "shoot" an armed man, he was more likely to be white than black. These differences occurred among both European American and African American participants but were most pronounced among those who held the strongest cultural stereotypes about blacks. In another study, police officers showed a similar pattern of results, except that the officers were not as quick as civilians were to shoot an unarmed black man (Correll et al., 2007).

Stereotyping often leads to **prejudice**, a positive or negative attitude toward an individual based simply on membership in some group (Maio et al., 2010). The literal meaning of the word *prejudice* is "prejudgment." Many theorists believe that prejudice, like other attitudes, has cognitive, affective, and behavioral components. Stereotyped thinking is the cognitive component of prejudicial attitudes. The hatred, admiration, anger, and other feelings people have about stereotyped groups make up the affective

stereotype a false assumption that all members of some group share the same characteristics.

prejudice A positive or negative attitude toward an entire group of people.

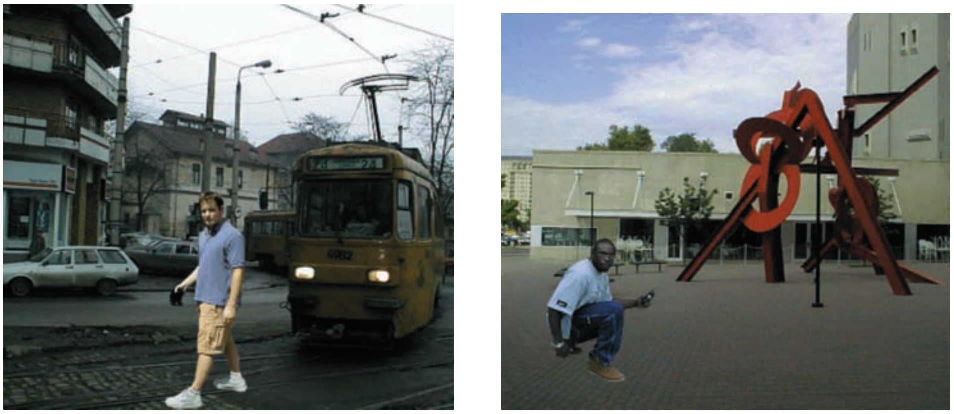

FIGURE 17.5

The Impact of Stereotypes on Behavior

TRY THIS When these men suddenly appeared on a video game screen, participants were supposed to "shoot" them, but only if they appeared to be armed (Correll et al., 2002). Stereotypes about whether white men or black men are more likely to be armed significantly affected the errors made by participants in firing their video game "weapons." Cover these photos with a pair of index cards; then ask a few friends to watch as you show each photo, one at a time, for just an instant, before covering it again. Then ask your friends to say whether either man appeared to be armed. Was one individual more often identified as armed? If so, which one?

component. The behavioral component of prejudice involves **social discrimination**, which is differing treatment of individuals who belong to different groups.

Theories of Prejudice and Stereotyping

Prejudice and stereotyping may occur for several reasons. Let's consider three explanatory theories, each of which has empirical support and accounts for some, but not all, instances of stereotyping and prejudice.

Motivational Theories For some people, prejudice against certain groups may enhance their sense of security and help them meet certain personal needs. This idea was first proposed by Theodor Adorno and his associates more than sixty years ago (Adorno et al., 1950). It has since been revised and expanded by Bob Altemeyer (2004; Altemeyer & Hunsberger, 2005). Specifically, these researchers suggest that prejudice may be especially likely among people who display a personality trait called *authoritarianism*. According to Altemeyer, authoritarianism is composed of three elements: (1) an acceptance of conventional or traditional values, (2) a willingness to unquestioningly follow the orders of authority figures, and (3) an inclination to act aggressively toward individuals or groups identified by these authority figures as threatening the values held by one's ingroup. People with an authoritarian orientation tend to view the world as a dangerous place (Cohrs & Ibler, 2009), and one way to protect themselves is to identify strongly with their ingroup and to dislike, reject, and perhaps even punish anyone who belongs to an outgroup (Thomsen, Green, & Sidanius, 2008). Looking down on and discriminating against outgroups—gay men and lesbians or African Americans, for example—may help people with authoritarian tendencies feel safer and feel better about themselves (Duckitt, 2006).

Another motivational explanation of prejudice employs the concept of social identity discussed earlier. Recall that whether they are authoritarian or not, most people are motivated to identify with their ingroup and tend to see it as better than other groups (Abrams & Hogg, 2010). As a result, members of an ingroup often see all members of outgroups as less attractive and less socially acceptable than ingroup members and may therefore treat them badly (Jackson, 2002). In other words, prejudice may result when people's motivation to enhance their own self-esteem causes them to disrespect other people.

Cognitive Theories Stereotyping and prejudice may also result from the social-cognitive processes people use in dealing with the world. There are so many other people, so many situations in which one meets them, and so many possible behaviors they might perform that we cannot possibly attend to and remember them all. Therefore, we use schemas and other cognitive shortcuts to organize and make sense out of our social world (Moskowitz, 2005). These cognitive processes allow us to draw accurate and useful conclusions about other people, but sometimes they

Schemas and Stereotypes

The use of schemas to assign certain people to certain categories can be helpful when deciding who is a customer and who is a store employee, but it can also lead to inaccurate stereotypes. Terrorist attacks and attempted attacks by Islamic extremists have led many people in the United States to think of all Muslims as terrorists and to discriminate against them. The problems that this false assumption has created for U.S. Muslims is yet another of the many damaging effects of Islamic terrorism.

lead to inaccurate stereotypes. For example, one effective way to deal with social complexity is to group people into *social categories*. Rather than remembering every detail about everyone we have ever encountered, we tend to put people into categories, such as "doctor," "senior citizen," "Republican," "student," or "Italian" (Dovidio, Kawakami, & Gaertner, 2000). To further simplify perception of these categories, we tend to see their members as being quite similar to one another. In fact, members of one ethnic group may find it harder to distinguish among specific faces within other ethnic groups than within their own group (Michel et al., 2006). People also tend to assume that all members of a particular group share the same beliefs and values and that those beliefs and values differ from their own (Dion, 2003). Finally, as noted in the chapter on perception, people's attention tends to be drawn to distinctive stimuli. Rude behavior by even a few members of an easily identified ethnic group may lead other people to see an *illusory correlation* between rudeness and ethnicity (Meiser & Hewstone, 2006). As a result, they may incorrectly believe that all members of that group are rude.

Learning Theories Like other attitudes, prejudice can be learned. Some prejudice is learned on the basis of conflicts between members of different groups, but people also develop negative attitudes toward groups with whom they have had little or no contact. Learning theories suggest that children can pick up prejudices just by watching and listening to parents, peers, and others (Castelli, Zogmaister, & Tomelleri, 2009; Rutland, Killen, & Abrams, 2010; Taylor, Peplau, & Sears, 2006). There may even be a form of *biopreparedness* (described in the learning chapter) that makes us especially likely to learn to fear people who are strangers or who look different from us (Kelly et al., 2007; Olson et al., 2001). Movies and television may also portray ethnic or other groups in ways that teach stereotypes and prejudice (Jost & Hamilton, 2005). For example, one study found that European American characters in popular television shows tend to behave more negatively toward African American characters than toward other European Americans. The study also found that watching these shows can elevate viewers' prejudice against African Americans in general (Weisbuch, Pauker, & Ambady, 2009). No wonder so many young children already know about the supposed negative characteristics of certain groups long before they ever meet members of those groups (Baron & Banaji, 2006; Degner & Wentura, 2010).

Reducing Prejudice

One clear implication of the cognitive and learning theories of prejudice and stereotyping is that members of one group are often ignorant or misinformed about the characteristics of people in other groups (Dovidio, Gaertner, & Kawakami, 2010). Before 1954, for example, most black and white children in the United States knew very little about one another because they went to separate schools. Then the Supreme Court declared that segregated public schools should be prohibited. By ruling segregation to be unconstitutional, the court created a real-life test of the **contact hypothesis**, which states that stereotypes and prejudice toward a group will diminish as contact with that group increases (Pettigrew & Tropp, 2006).

Did the desegregation of U.S. schools confirm the contact hypothesis? In a few schools, integration was followed by a decrease in prejudice, but in most places, either no change occurred or prejudice actually increased (Oskamp & Schultz, 1998). However, these results did not necessarily disprove the contact hypothesis. In-depth studies of schools in which desegregation was successful suggested that contact alone was not enough. Integration reduced prejudice only when certain social conditions were created (Pettigrew & Tropp, 2006). First, members of the two groups had to be of roughly equal social and economic status. Second, school authorities had to promote cooperation and interdependence between the members of different ethnic groups by having them work together on projects that required relying on one another for success. Third, the contact between group members had to occur on a one-on-one basis. It was only when people got to know one another as individuals that the errors contained in stereotypes became apparent. When these conditions were met, the children's attitudes toward one another became more positive. The same effects have appeared in adults in the United States and elsewhere. In Italy, for example, people who had equal-status contact with black immigrants from North Africa displayed less prejudice against them than Italians who had no contact with those immigrants (Kirchler & Zani, 1995).

Elliot Aronson (1997) describes a teaching strategy, called the *jigsaw technique,* that helps create the conditions that reduce prejudice. The strategy calls for children from several ethnic groups to work as a team to complete a task, such as writing a report about a famous person in history. Each child learns a separate piece of information about this person, such as place of birth, and provides this information to the team. Studies show that children from various ethnic groups who are exposed to the jigsaw technique and other cooperative learning experiences show substantial reductions in prejudice toward other groups (Aronson, 1997). The success reported in

Fighting Ethnic Prejudice

Negative attitudes about members of ethnic groups are often based on negative personal experiences or the negative experiences and attitudes people hear from others. Cooperative contact between equals can help promote mutual respect and reduce ethnic prejudice. Even *imagining* this kind of contact may help (Crisp & Turner, 2009).

contact hypothesis The idea that stereotypes and prejudice toward a group will diminish as contact with the group increases.

these studies has greatly increased the popularity of cooperative learning exercises in classrooms in the United States. Such exercises may not eliminate all aspects of ethnic prejudice in children, but they seem to be a step in the right direction.

Can friendly, cooperative, interdependent contact reduce the more entrenched forms of prejudice seen in adults? It may. When equal-status adults work jointly toward a common goal, bias and distrust can be reduced, particularly among those in ethnic majority groups (Tropp & Pettigrew, 2005). This is especially true if they come to see themselves as members of the same group rather than as belonging to opposing groups (Gaertner, Dovidio, & Houlette, 2010). The challenge to be met in creating such cooperative experiences in the real world is that the participants must be of equal status—a challenge made more difficult in many countries by the sizable status differences that still exist between ethnic groups (Kenworthy et al., 2006).

In the final analysis, contact provides only part of the solution to the problems of stereotyping, prejudice, and discrimination. To reduce ethnic prejudice, we must develop additional educational techniques that address the social cognitions and perceptions that lie at the core of bigotry and hatred toward people who are different from ourselves (Amodio & Devine, 2009; Bigler & Liben, 2007).

THINKING CRITICALLY

Is Ethnic Prejudice Too Ingrained Ever to Be Eliminated?

Overt ethnic prejudice has decreased dramatically in the United States over the past fifty to sixty years. For example, in the 1950s, fewer than half of European American college students surveyed said they were willing to live in integrated neighborhoods; more recent surveys indicate that about 95 percent now say they would be willing to do so. And four decades ago, fewer than 40 percent of European Americans said they would vote for an African American presidential candidate (Dovidio & Gaertner, 1998); in 2008, an African American president was elected. Despite these changes, research in social psychology suggests that more subtle aspects of prejudice and discrimination may remain as entrenched in the United States today as they were a couple of decades ago (Dovidio, Gaertner, & Kawakami, 2010).

LINKAGES Can we ever be unbiased about anyone? (a link to Consciousness, p. 334)

What am I being asked to believe or accept?

Even people who see themselves as unprejudiced and who disavow ethnic stereotypes and discrimination still hold negative stereotypes about ethnic outgroups and in certain situations will display prejudice and discrimination toward them (Dovidio et al., 2009). Some people claim, therefore, that negative attitudes toward ethnic outgroups are so deeply ingrained in all of us that ethnic prejudice can never be eliminated.

What evidence is available to support the assertion?

Evidence for this assertion focuses primarily on prejudice against African Americans by European Americans. It comes, first, from studies testing the theory of *aversive racism* (Dovidio & Gaertner, 2008). This theory holds that even though many European Americans consider ethnic prejudice unacceptable or aversive, they still sometimes display it—especially when they can do so without admitting, even to themselves, that they are prejudiced.

LINKAGES Can subliminal stimuli influence our judgments about people? (a link to Perception, p. 161)

In one test of this theory, a male experimenter telephoned male and female European Americans who were known to believe in ethnic equality. The man claimed to be a stranded motorist who was trying to call a service station from a pay phone. When told he had called the wrong number, the man replied that he was out of coins and asked the person he'd reached to call a service station for him. If people listened long enough to learn of the man's problem, they were just as likely to contact the service station whether the caller "sounded" European American or African American. However, if the caller "sounded" African American, these supposedly unprejudiced people were almost five times as likely to hang up even before the caller could ask for help (Gaertner & Dovidio, 1986). More recent studies have reported similar results (e.g., Kunstman & Plant, 2008).

A second line of evidence for the entrenched nature of prejudice comes from research showing that many people hold negative stereotypes about ethnic minorities but are unaware that they do so. These negative stereotypes can also be *activated* without conscious awareness, even among people who believe they are free of prejudice (Fiske & Taylor, 2008). For example, physicians who were not conscious of their bias against African Americans were found to behave more negatively toward their African American patients, which in turn caused these patients to react negatively toward these doctors (Penner et al., 2010). Other researchers have used the priming procedures described in the chapter on consciousness to activate unconscious thoughts and feelings that can alter people's reactions to stimuli without their awareness. In one study, white participants were exposed to subliminal presentations of pictures of black individuals (Chen & Bargh, 1997). The participants were not consciously aware that they had seen these pictures, but when they interacted with a black man soon afterward, those who had been primed with the pictures acted more negatively toward him and saw him as more hostile than people who had not been primed. Priming apparently activated these participants' negative ethnic stereotypes. It is also possible to prime unconscious negative stereotypes about other groups, including women and people who are overweight (Glick & Fiske, 2001; Degner & Wentura, 2009). All of these findings suggest that stereotypes are so well learned and so ingrained in people that they may be activated automatically and without conscious awareness (Amodio & Devine, 2009).

Are there alternative ways of interpreting the evidence?

The evidence presented so far suggests that it may be impossible to eliminate ethnic prejudice because everyone harbors unconscious negative stereotypes about various groups. But this evidence does not necessarily mean that unconscious stereotypes affect everyone in the same way. Perhaps they have a greater impact on people who are more overtly prejudiced.

What additional evidence would help evaluate the alternatives?

One way to evaluate this possibility is to compare the responses of prejudiced and unprejudiced people in various experimental situations. In one mock-trial study, for example, overtly prejudiced white jurors recommended the death penalty more often for black defendants than for white defendants found guilty of the same crime. Low-prejudice white jurors showed this bias only when they believed that a black member of the jury also favored giving the death penalty (Dovidio et al., 1997). Priming studies, too, show that although negative stereotypes can be primed in both prejudiced and unprejudiced people, it is easier to do in people who openly display their ethnic bias (Dovidio & Gaertner, 2010). Furthermore, activation of these stereotypes may be less likely to affect the conscious attitudes and behavior of unprejudiced people. So when unconscious stereotypes are activated in unprejudiced people, the effects tend to appear in subtle ways, such as in facial expressions or other nonverbal behaviors (Kawakami, Dion, & Dovidio, 1998; Lepore & Brown, 1997; Vanman et al., 2004).

What conclusions are most reasonable?

Taken together, research evidence presents a mixed picture regarding the possibility of eliminating ethnic prejudice. True, people in the United States are not nearly as colorblind as we might hope, and ethnic prejudice may be so ingrained in some people as to be subconscious. However, research suggests that it may still be possible to eliminate even subconscious stereotypes (Kawakami, Dovidio, & van Kamp, 2005; Kawakami et al., 2007). It also appears that when unprejudiced people are made aware of their negative beliefs about some target group, they will actively work to prevent those beliefs from influencing their behavior toward members of that group (Monteith, Arthur, & Flynn, 2010; Payne, 2008). In short, prejudice is ingrained, but it can also be reduced, and it makes sense to do everything possible to reduce it. In the United States, as in any multicultural country, survival as a civilized society requires that we all continue to fight against overt and covert forms of stereotyping, prejudice, and social discrimination. This goal is more important than ever as the fight against international terrorism can make it all too easy to misjudge and mistreat innocent people based on their ethnicity.

Interpersonal Attraction

Research on prejudice suggests some of the reasons why people, from childhood on, may come to dislike or even hate other people. An equally fascinating aspect of social cognition is why people like or love other people. Folklore tells us that "opposites attract" but also that "birds of a feather flock together." Although valid to some degree, neither of these statements is entirely accurate in all cases. We begin our coverage of interpersonal attraction by discussing the factors that lead to initial attraction. We then examine how liking sometimes develops into more intimate relationships.

Keys to Attraction

Whether you like someone or not depends partly on situational factors and partly on personal characteristics.

The Environment One of the most important determinants of attraction is simple physical proximity (Clark & Lemay, 2010). As long as you do not initially dislike a person, your liking for that person will increase with additional contact. This effect was apparent in a study in which unacquainted students were randomly assigned to classroom seats. A year later, these students were shown photos of everyone in that class and were asked to rate their liking of each one. The ratings showed that students who sat next to each other or in the same row liked one another more than students who were seated farther away (Back, Schmukle, & Egloff, 2008). Another study found that we even tend to like people who *resemble* those who have often been near us (Rhodes, Halberstadt, & Brajkovich, 2001). This proximity phenomenon—another example of the *mere-exposure effect* mentioned earlier—helps account for the fact that next-door neighbors are usually more likely to become friends than people who live farther from one another. Chances are, most of your friends are people whom you met as neighbors, coworkers, or classmates (Liben-Nowell et al., 2005).

The circumstances under which people first meet also influence attraction. In accordance with the conditioning principles discussed in the chapter on learning, you are much more likely to be attracted to a stranger if you meet in comfortable, rather than uncomfortable, physical conditions (IJzerman & Semin, 2009). Similarly, if you are rewarded in the presence of a stranger, the chances that you will like that stranger are increased, even if the stranger was not the one who gave the reward. In one study, for example, an experimenter judged people's creativity while another person watched. Compared with those who received a negative evaluation, participants who were evaluated positively tended to like the observer more (Griffitt & Guay, 1969). At least among strangers, then, liking can occur by associating a person with something pleasant.

Proximity and Liking

TRY THIS Research on environmental factors in attraction suggests that, barring bad first impressions, the more often we make contact with someone—as neighbors, classmates, or coworkers, for example—the more we tend to like that person. Does this principle apply in your life? To find out, think about how and where you met each of your closest friends. If you can think of cases in which proximity did not lead to liking, what do you think interfered with the formation of friendship?

Similarity People also tend to like those they perceive as similar to themselves on variables such as age, religion, smoking or drinking habits, or being a "morning" or "evening" person (Clark & Lemay, 2010). Similarity in attitudes is an especially important influence on attraction. This relationship has been found among children, college students, adult workers, and senior citizens (Taylor, Peplau, & Sears, 2006).

Similarity in attitudes toward mutual acquaintances is a particularly good predictor of liking because people generally prefer relationships that are *balanced*. As illustrated in Figure 17.6, if Zoë likes Abigail, the relationship is balanced as long as they agree on their evaluation of a third person, Samantha, regardless of whether they like or dislike that third person. However, the relationship will be imbalanced if Zoë and Abigail disagree on their evaluation of the third person.

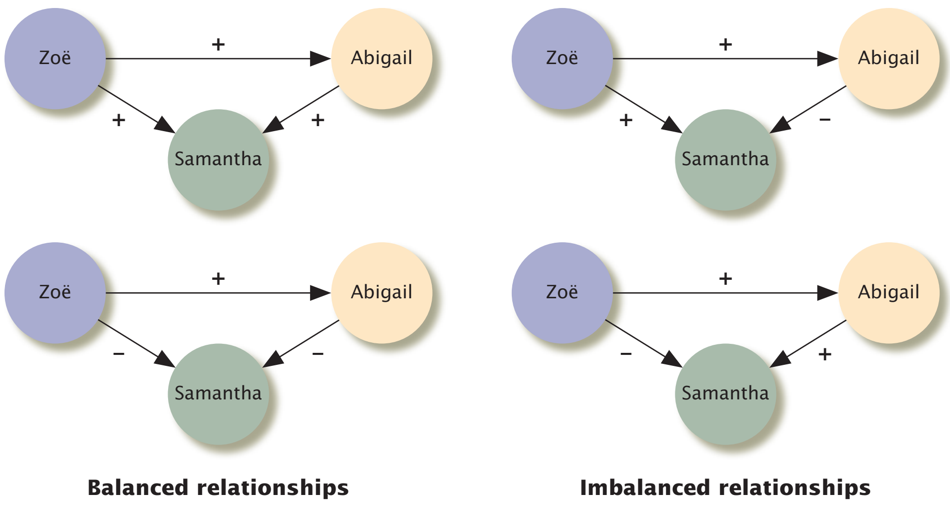

FIGURE 17.6

Balanced and Imbalanced Relationships

TRY THIS Here are some common examples of balanced and imbalanced patterns of relationships among three people. The plus and minus signs refer to liking and disliking, respectively. Balanced relationships are comfortable and harmonious. Imbalanced ones often bring conflict. Take a moment to think about the balanced and imbalanced relationships that exist in your life or in the lives of people you know.

One reason why we like people with similar views of the world is that we expect such people to approve of us (Condon & Crano, 1988). But it's hard to say whether attraction is a cause or an effect of similarity. For example, you might like someone because his attitudes are similar to yours, but it is also possible that as a result of liking him, your attitudes will become more similar to his (Davis & Rusbult, 2001). Even if your own attitudes don't change, you may change your *perceptions* of the liked person's attitudes such that those attitudes seem more similar to yours (Brehm, 1992).

Physical Attractiveness Physical characteristics are another important factor in attraction, particularly during the initial stages of a relationship (Leary, 2010). From preschool through adulthood, physical attractiveness is a key to popularity with members of both sexes (e.g., Langlois et al., 2000). Consistent with the **matching hypothesis** of interpersonal attraction, however, people tend to date, marry, or form other committed relationships with those who are similar to themselves in physical attractiveness (Yela & Sangrador, 2001). One possible reason for this outcome is that people tend to be most attracted to those with the greatest physical appeal, but they also want to avoid being rejected by such individuals. So it may be compromise, not preference, that leads people to pair off with those who are roughly equivalent to themselves in physical attractiveness (Carli, Ganley, & Pierce-Otay, 1991; Kavanagh, Robins, & Ellis, 2010, Lee et al., 2008).

Intimate Relationships and Love

There is much about intimate relationships that psychologists do not—and may never—understand, but they are learning all the time. As mentioned in the chapter on motivation and emotion, evolutionary psychologists suggest that men and women employ different mating strategies and that each sex looks for different attributes in a potential mate (Buss, 2008; Neuberg, Kenrick, & Schaller, 2010). For example, in short-term relationships at least, women may be much more selective than men about the intelligence of their partners (Buss, 2008; see Figure 17.7).

Intimate Relationships Eventually, people who are attracted to each other usually become *interdependent,* which means that the thoughts, emotions, and behaviors of one person affect the thoughts, emotions, and behaviors of the other (Clark & Lemay, 2010). Interdependence is one of the defining characteristics of intimate relationships.

Another key component of successful intimate relationships is *commitment,* which is the extent to which each party is psychologically attached to the relationship and wants to remain in it (Amodio & Showers, 2005). People feel committed to a relationship when they are satisfied with the rewards they receive from it, when they have

matching hypothesis The notion that people are most likely to form relationships with those who are similar to themselves in physical attractiveness.

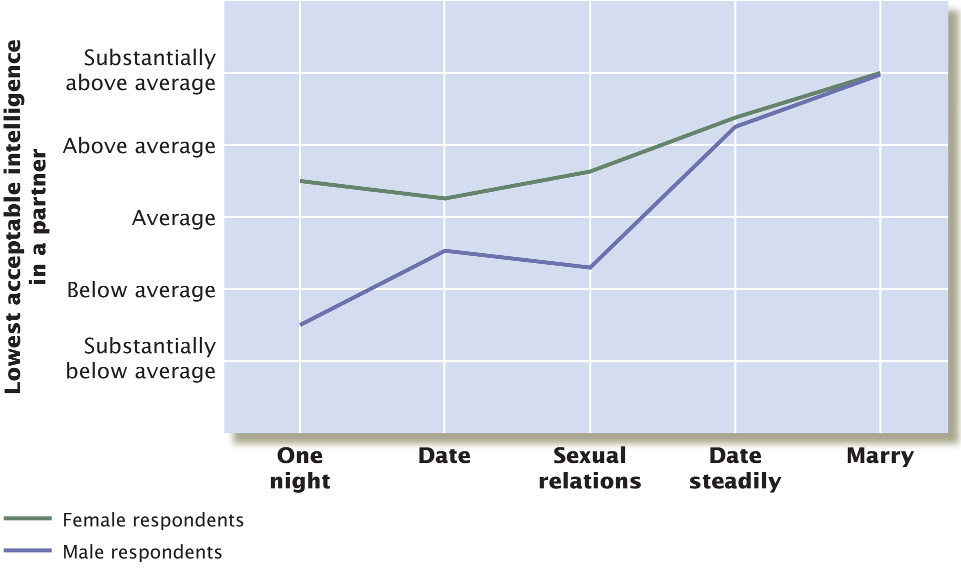

FIGURE 17.7

Sex Differences in Date and Mate Preferences

According to evolutionary psychologists, men and women have developed different strategies for selecting sexual partners. These psychologists say that women became more selective than men because they can have relatively few children and want a partner who is able to help care for those children. Here are some data supporting this idea. When asked about the intelligence of people they would choose for one-night stands, dating, and sexual relationships, women preferred much smarter partners than men did. Only when the choices concerned steady dating and marriage did the men's preference for bright partners equal that of the women. Critics of the evolutionary approach explain such sex differences as reflecting learned social norms and expectations of how men and women should behave (Eagly & Wood, 1999; Miller, Putcha-Bhagavatula, & Pedersen, 2002).

Source: Kenrick et al. (1993).

invested significant tangible and intangible resources in it, and when there are few attractive alternative relationships available to them (Bui, Peplau, & Hill, 1996; Lydon, Fitzsimmons, & Naidoo, 2003).

Analyzing Love Although some people think love is simply a strong form of liking, research suggests that romantic love and liking are quite separate emotions, at least in the sense that they are associated with differing patterns of brain chemistry and brain activity (Aron et al., 2005; Emanuele et al., 2006). And although romantic love and sexual desire are often experienced together, they, too, seem to be separate emotions associated with different patterns of physiological arousal (Diamond, 2004). Further, most theorists agree that there are several different types of love (Berscheid, 2010). One widely accepted view distinguishes between *romantic* or *passionate love* and *companionate love* (Berscheid, 2011). Passionate love is intense, arousing, and marked by both strong physical attraction and deep emotional attachment. Sexual feelings are strong, and thoughts of the loved one intrude frequently on a person's awareness. Companionate love is less arousing but psychologically more intimate. It is marked by mutual concern for the welfare of the other (Berscheid, 2010).

Robert Sternberg (1997) has offered an even broader analysis of love. According to his *triangular theory,* the three basic components of love are *passion, intimacy,* and *commitment.* Various combinations of these components result in different types of love, as illustrated in Figure 17.8. For example, Sternberg suggests that *romantic love* involves a high degree of passion and intimacy but lacks substantial commitment to the other person. *Companionate love* is marked by a great deal of intimacy and commitment but little passion. *Consummate love* is the most complete and satisfying. It is the most complete because it includes a high level of all three components, and it is the most satisfying because the relationship is likely to fulfill many of the needs of each partner. Sternberg has more recently advanced a "duplex theory" of love by pairing his triangular theory with a second one that focuses on love as a story. This second theory focuses on the idea that in Western cultures at least, the success of a relationship appears to depend not just on its perceived characteristics but also on the degree to which those characteristics fit each partner's ideal story of love, whether it be that of a prince and princess or a pair of business partners, for example (Sternberg, 2006).

Cultural factors have a strong influence on the value that people place on love. In North America and the United Kingdom, for example, the vast majority of people believe that they should love the person they marry. By contrast, in India and Pakistan,

FIGURE 17.8

A Triangular Theory of Love

According to Robert Sternberg, different types of love result when the three basic components in his triangular theory occur in different combinations. The size of the triangle of love increases as love increases, and its shape is determined by the relative strength of each basic component. The perfectly balanced triangle shown in the center of this figure depicts a relationship in which all three components are of about equal strength.

Liking = Intimacy Alone (true friendship without passion or long-term commitment)
Romantic Love = Intimacy + Passion (lovers physically and emotionally attracted to each other but without commitment, as in a summer romance)
INTIMACY
Companionate Love = Intimacy + Commitment (long-term committed friendship such as a marriage in which the passion has faded)
Consummate Love = Intimacy + Passion + Commitment (a complete love consisting of all three components—an ideal difficult to attain)
PASSION
COMMITMENT
Infatuation = Passion Alone (passionate, obsessive love at first sight without intimacy or commitment)
Empty Love = Commitment Alone (decision to love another without intimacy or passion)
Fatuous Love = Passion + Commitment (commitment based on passion but without time for intimacy to develop—shallow relationship such as a whirlwind courtship)

about half the people interviewed in a survey said they would marry someone they did not love if that person had other qualities that they desired (Levine et al., 1995). Many such cultural differences in the role of love in marriage are likely to continue, but some of them, such as the differences that had once existed between the United States and China, seem to be disappearing (Hatfield & Rapson, 2006).

Strong and Weak Marriages Long-term studies of successful and unsuccessful marriages suggest that premarital attitudes and feelings predict marital success. For example, one study found that couples who had a close, intimate relationship and similar attitudes when they were dating were more likely still to be married fifteen years later (Hill & Peplau, 1998; Neff & Karney, 2005). Also, still-married couples were more likely to have had a premarital relationship that was rewarding and balanced.

A Wedding in India

TRY THIS Most people in Western cultures tend to marry a person whom they choose on the basis of love, sometimes without regard for differences between them in religion, ethnicity, and financial or social status. In other cultures, however, these sociocultural considerations—and even arrangements made by parents—may largely determine who marries whom. Make a list of the factors that you think may have brought this couple together.

Happy and Healthy

TRY THIS People in marriages and other long-term relationships that are satisfying tend to enjoy better physical and psychological health than those in unsatisfying relationships. In light of research described in the chapter on health, stress, and coping, make a list of reasons why this might be the case.

Among married couples, women—but not men—generally tend to be more satisfied with their marriage when the partners talk a lot about the relationship (Acitelli, 1992). Partners in successful marriages also tend to share each other's view of themselves and the other, even if that view is a negative one (Swann, De La Ronde, & Hixon, 1994). The perception that the relationship is fair and equitable also enhances marital satisfaction, especially for women (De Maris, 2007). After the birth of a first child, for example, many wives find that they have much more work than they had anticipated. If their husbands do not share this work to the degree they expected, wives' marital satisfaction tends to decrease (Doss et al., 2009; McNulty & Karney, 2004).

One particularly interesting line of research suggests that even brief observations of couples' interactions can predict whether those couples will divorce and when (Driver & Gottman, 2004). Among couples who divorced relatively soon after marriage, the partners tended to express both positive and negative feelings toward one another, but they were unable to control the way they expressed these feelings, especially the negative ones. Communication became increasingly hurtful and eventually broke down (Driver et al., 2003). A different picture emerged, however, in couples who divorced after many years of marriage. These people did not necessarily express negative emotions toward one another. They simply became less and less likely to communicate *any* feelings. The increasing emotional distance between the spouses created a sense of isolation that eventually led to divorce (Gottman & Levenson, 2002). These findings can help us understand why people in a long and apparently strong marriage—such as Al and Tipper Gore—might suddenly announce that they are divorcing, and why they may remain friends afterward. These people may still like each other but no longer love each other (Gottman & Levenson, 2000; Huston et al., 2001).

LINKAGES

As noted in the chapter on introducing psychology, all of psychology's many subfields are related to one another. Our discussion of brain activity and attitudes illustrates just one way in which the topic of this chapter, social cognition, is linked to the subfield of biological psychology (see the chapter on biological aspects of psychology). The Linkages diagram shows ties to two other subfields as well, and there are many more ties throughout the book. Looking for linkages among subfields will help you see how they all fit together and better appreciate the big picture that is psychology.

Consciousness
CHAPTER 12
Human Development

SUMMARY

Social cognition (the mental processes through which people perceive and react to others) is one aspect of *social psychology* (the study of how people influence and are influenced by other people).

Social Influences on the Self

People's social and cultural environments affect their thoughts and feelings about themselves, including their *self-esteem* and their *self-concept.*

Social Comparison

When people have no objective criteria by which to judge themselves, they engage in *social comparison* (to others) or temporal comparison (to themselves at an earlier time) as their standard. Such comparison can affect self-evaluation or self-esteem. Categories of people that are habitually used for social comparison are known as *reference groups.* Comparison to reference groups sometimes results in a sense of *relative deprivation,* which can in turn cause personal and social turmoil.

Social Identity Theory

A person's *social identity* is formed from beliefs about the groups to which the person belongs. Social identity affects the beliefs we hold about ourselves. It permits us to feel part of a larger group, engendering loyalty and sacrifice from group members but also potentially engendering bias and discrimination toward people who are not members of the group.

Social Perception

Social perception concerns the processes by which people interpret information about others, form impressions of them, and draw conclusions about the reasons for their behavior.

The Role of Schemas

Schemas, the mental representations about people and social situations that we carry into social interactions, affect what we pay attention to, what we remember, and how we judge people and events.

First Impressions

First impressions are formed easily and quickly, in part because people apply existing schemas to their perceptions of others. First impressions change slowly because once we form an impression about another person, we try to maintain it. Schemas, however, can create *self-fulfilling prophecies,* leading people to act in ways that bring out in others behavior that is consistent with expectations.

Explaining Behavior: Attribution

Attribution is the process of explaining the causes of people's behavior, including our own. Observers tend to attribute behavior to causes that are either internal or external to the actor. In general, they do this by looking at three aspects of the behavior: consensus, consistency, and distinctiveness. People from different cultures may sometimes reach different conclusions about the reasons for an actor's behavior.

Errors in Attribution

Attributions are affected by errors that systematically distort one's view of behavior. The most common attributional errors are the *fundamental attribution error* (and its cousin, the ultimate attribution error), the *actor-observer effect,* and the *self-serving bias.* Personal and cultural factors can affect the extent to which people exhibit attributional errors.

The Self-Protective Functions of Social Cognition

People often avoid admitting something threatening about themselves through unrealistic optimism and a feeling of unique invulnerability.

Attitudes

An *attitude* is the tendency to respond positively or negatively to a particular object. Attitudes affect a wide range of behaviors.

The Structure of Attitudes

Many theorists believe that attitudes are made up of cognitive components (beliefs), affective components (feelings), and behavioral components (actions). However, it is often difficult to predict a specific behavior from a person's beliefs or feelings about an object. Cognitive theories propose that attitudes consist of evaluations of an object that are stored in memory. This approach suggests that the likelihood of attitude-behavior consistency depends on the accessibility of evaluations in memory, on subjective norms, on perceived control over the behavior, and on prior direct experience with the attitude object.

Forming Attitudes

Attitudes can be learned through modeling, as well as through classical or operant conditioning. They are also subject to the mere-exposure effect: All else being equal, people develop greater liking for a new object the more often they are exposed to it.

Changing Attitudes

The effectiveness of a persuasive message in changing attitudes is influenced by the characteristics of the person who communicates it, its content, and the audience receiving it. The *elaboration likelihood model* suggests that attitude change can occur through either a peripheral or a central route, depending on a person's ability and motivation to consider an argument carefully. Another approach is to change a person's behavior in the hope that the person's attitude will be adjusted to match the behavior. *Cognitive dissonance theory* holds that if inconsistency between attitudes and behavior creates discomfort related to a person's self-concept or self-image, the person will be motivated to reduce that discomfort. *Self-perception theory* suggests that such attitude changes occur in some cases as people look to their behavior for clues about what their attitudes are.

Prejudice and Stereotypes

Stereotypes often lead to *prejudice* and *social discrimination.*

Theories of Prejudice and Stereotyping

Motivational theories of prejudice suggest that some people have a need to disrespect and dislike others. This need may stem from the trait of authoritarianism or from a strong social identity. In either case, feeling superior to members of outgroups makes these people feel better about themselves. As a result, *ingroup* members tend to discriminate against members of *outgroups.* Cognitive theories suggest that people categorize others into groups in order to reduce social complexity. And learning theories maintain that stereotypes, prejudice, and discriminatory behaviors can be learned from parents, peers, and the media.

Reducing Prejudice

The contact hypothesis proposes that intergroup contact can reduce prejudice and lead to more favorable attitudes toward a stereotyped group—but only if the contact occurs under specific conditions, as when there is equal status between group members. Helping diverse people feel as if they belong to the same group can also reduce intergroup prejudice.

Interpersonal Attraction

Keys to Attraction

Interpersonal attraction is a function of many variables. Physical proximity is important because it allows people to meet. The situation in which they meet is important because positive or negative aspects of the situation tend to be associated with the other person. Characteristics of the other person are also important. Attraction tends to be greater when two people share similar attitudes and characteristics. Physical appearance plays a role in attraction. Initially, attraction is strongest to those who are most physically attractive. But for long-term relationships, the *matching hypothesis* applies: People tend to choose others whose physical attractiveness is about the same as theirs.

Intimate Relationships and Love

A defining characteristic of intimate relationships is interdependence, and a key component of successful relationships is commitment. Commitment is in turn affected by the rewards coming from the relationship, the resources invested in it, and the possible alternatives open to each party. Robert Sternberg's triangular theory suggests that love is a function of three components: passion, intimacy, and commitment. Varying combinations of these components create different types of love. Couples who have long and successful marriages are likely to perceive the relationship as fair to both parties, and they are likely to share warm and loving feelings for each other.

LINKAGES TO FURTHER LEARNING

Now that you have finished reading this chapter, how about exploring some of the topics and information that you found most interesting? Here are some places to start.

Books

Henry Louis Gates Jr., *Colored People: A Memoir* (Vintage, 1994). Growing up black in segregated West Virginia.

Alex Kotlowitz, *The Other Side of the River: A Story of Two Towns, a Death, and America's Dilemma* (Doubleday, 1998). A story of social discrimination in law enforcement and prejudice in a town that is racially and geographically divided.

Charles Stangor (Ed.), *Stereotypes and Prejudice: Essential Readings* (Psychology Press, 2000). A collection of research articles on prejudice.

TALKING POINTS

Here are a few talking points to help you summarize this chapter for family and friends without giving a lecture.

1. Our expectations about how someone will behave can not only shape our first impression of that person but also lead the person to behave in line with our expectations.
2. We often take personal credit when we succeed at something but blame circumstances when we fail.
3. Many people ignore the dangers of risky behavior because unrealistic optimism leads them to believe that bad things only happen to other people.
4. When our actions are in conflict with our attitudes or beliefs, we tend to reduce the conflict by adjusting our attitudes, not our behavior.
5. A feeling of belonging to a particular social or ethnic group is comforting, but it can also lead to prejudice against people in other groups.
6. Some people find that being prejudiced helps them feel better about themselves while making the world seem simpler and easier to deal with.
7. Although we might prefer to have the most physically attractive partners available, most people compromise by forming intimate relationships with someone whose attractiveness is similar to their own.

SUMMARY

If you are like most people, there is probably at least one thing you do in private that you would never do when someone else is around. In this chapter, we describe many other ways in which the presence and behavior of other people affect our own behavior and how we in turn affect the behavior of others.

In the days following the September 11, 2001, attacks on the World Trade Center and the Pentagon, cities throughout the United States experienced a substantial increase in false bomb threats and other "copycat" crimes apparently inspired by the terrorists' actions. Unfortunately, this phenomenon is not unusual. After the murderous rampage at Columbine High School in April 1999, for example, a number of students at other high schools were arrested for threatening similar acts of violence against their classmates. Copycat threats were also made following the horrific massacre at Virginia Tech in April 2007. Well-publicized suicides, and assisted suicides too, are often copied (Frie et al., 2003; Romer, Jamieson, & Jamieson, 2006). Even telecasts of major professional boxing matches are typically followed by a small increase in murders.

Do these correlations mean that media coverage of violence triggers copycat violence? As described in the chapter on learning, televised violence can play a causal role in aggressive behavior, but there are additional reasons to believe that when suicides and murders become media events, they stimulate people to imitate them. For one thing, many of the people who kill themselves soon after a notable suicide are about the same age and the same gender as the original victim (Cialdini, 2007). Further, murder victims in the days following a professional championship fight are likely to be members of the same ethnic group as the losing boxer (Miller et al., 1991).

Copycat, or imitative, crimes illustrate **social influence**, the process through which a person's thoughts, feelings, and behavior are directly or indirectly affected by the words or actions of other people (Hogg, 2010). In this chapter, we describe its more positive aspects too, beginning with a discussion of social influence itself. We then consider several related aspects of how we are influenced by others, including the processes of conformity, compliance, and obedience. Then we explore the causes and consequences of aggression, helping, and altruism. Finally, we examine circumstances in which people jointly influence one another's behavior, especially circumstances in which people compete with one another for some scarce resource or work together in groups to solve some problem.

Social Influence

Copycat crimes are but one illustration of the fact that people can influence the way other people think, feel, and act, even without specifically trying to do so. There are countless others. For example, the amount of food that people order in a restaurant can be affected by the weight of the person who is eating with them. They tend to order a smaller portion than the other person does if that person is obese but to order items of about the same size if the other person is slender (McFerran et al., 2010). The most widespread yet subtle form of social influence is communicated through social norms.

Social norms are learned, socially based rules that prescribe what people should or should not do in various situations (Hogg, 2010). These norms are transmitted by parents, teachers, clergy, peers, and other agents of culture. Although they often

social influence The process whereby one person's behavior is affected by the words or actions of others.

social norms Socially based rules that prescribe what people should or should not do in various situations.

cannot be verbalized, norms are so powerful that people usually follow them automatically. At movie theaters in North America and Britain, for example, social norms tell us that we should get in line to buy a ticket rather than crowd around the ticket window; they also lead us to expect that others will do the same. By informing people of what is expected of them and others, social norms make social situations less uncertain and more comfortable (Schultz et al., 2007).

Robert Cialdini (2007) has described social norms as either descriptive or injunctive. *Descriptive norms* indicate how most other people actually behave in a given situation. They tell us what actions are common in the situation and thereby implicitly give us permission to act in the same way. The fact that most people do not cross a street until the green light or "walk" sign appears is an example of a descriptive norm. *Injunctive norms* give more specific information about the actions that others find acceptable and those that they find unacceptable. Subtle pressure exists to behave in accordance with these norms. A sign that reads "Do not cross on red" or the person next to you saying the same thing is an example of an injunctive norm. Sometimes both kinds of norms operate at the same time. There is evidence, for example, that how much college students use tobacco and alcohol is influenced both by how much they think other students drink and smoke (descriptive norms) and whether they think that their close friends approve of these behaviors (injunctive norms) (Etcheverry & Agnew, 2008; Neighbors et al., 2008).

© AP Photo

Clothing and Culture

The social norms that guide how people dress and behave in various situations are part of the culturally determined socialization process described in the chapter on human development. The process is the same worldwide. Parents, teachers, peers, religious leaders, and others communicate their culture's social norms to children, but differences in those norms result in quite different behaviors from culture to culture.

One very powerful injunctive norm is *reciprocity,* the tendency to respond to others as they have acted toward you (Kenrick, Neuberg, & Cialdini, 2010). Restaurant servers often exploit this social norm by leaving some candy with the bill. Customers who receive this gift tend to reciprocate by leaving a larger tip than customers who don't get candy (Strohmetz et al., 2002). The reciprocity norm probably exists in every culture, but other social norms are not universal (Miller, 2001). For instance, people around the world differ greatly in terms of the physical distance they maintain between themselves and others during conversation. People from South America usually stand much closer to one another than people from North America do. And as suggested in the chapter on psychological disorders, behavior considered normal and friendly in one culture may be seen as abnormal or even offensive in another.

The social influence exerted by norms creates orderly social behavior. But social norms can also lead to a breakdown in order. For example, **deindividuation** is a phenomenon in which a person becomes "submerged in a group" and loses the sense of individuality (Kenrick, Neuberg, & Cialdini, 2010). When people experience deindividuation, they become emotionally aroused and feel intense closeness with the group. This increased awareness of group membership may create greater adherence to the group's norms, even if those norms promote antisocial behavior. In other words, through deindividuation, people appear to become "part of the herd," and they may perform acts that they would not do otherwise. Fans at rock concerts and athletic events have trampled one another to death in their frenzy to get the best seats. Normally mild-mannered people may find themselves throwing rocks or fire bombs at police during political protests.

The greater the sense of personal anonymity, the more influence the group appears to have (Lea, Spears, & de Groot, 2001). An analysis of newspaper accounts of lynchings in the United States over a fifty-year period showed that larger lynch mobs were more savage and vicious than smaller ones (Mullen, 1986). Deindividuation provides an example of how, given the right circumstances, quite normal people can engage in destructive, even violent, behavior.

deindividuation A psychological state occurring in group members that results in loss of individuality and a tendency to do things not normally done when alone.

LINKAGES

LINKAGES Do people perform better or worse when others are watching? (a link to Motivation and Emotion, p. 737)

Motivation and the Presence of Others

In the chapter on motivation and emotion, we noted that social factors such as parental attitudes toward achievement often affect motivation. But a person's current motivational state is also affected by the mere presence of other people. Consider what was probably the first experiment in social psychology, conducted by Norman Triplett in 1897.

© David Leeson/The Image Works

Deindividuation

Robes, hoods, and group rituals help create deindividuation in these Ku Klux Klansmen by focusing their attention on membership in their organization and on its values. The hoods also hide their identities, which reduces their sense of personal responsibility and accountability and makes it easier for them to engage in hate crimes and other cowardly acts of bigotry. Deindividuation operates in other groups too, ranging from lynch mobs and terrorist cells to political protesters and urban rioters. In short, people who feel that they are anonymous members of a group may engage in antisocial acts that they might not perform on their own.

Triplett noticed that bicycle racers tended to go faster when other racers were nearby than when they were alone. Did seeing one another remind the racers of the need to go faster to win? To test this possibility, Triplett arranged for bicyclists to complete a 25-mile course under three conditions: riding alone in a race against the clock, riding with another cyclist but not in competition, or competing directly with another rider. The cyclists went much faster when another rider was present than when they were simply racing against time. This was true even when they were not competing against the other person. Something about the presence of the other person, not just competition, produced increased speed.

The term **social facilitation** describes circumstances in which, as in the bicycle racing example, the mere presence of other people can improve performance. This improvement does not always occur, however. The presence of other people sometimes hurts performance, a process known as **social interference**. For decades, these results seemed contradictory. Then Robert Zajonc (pronounced "ZY-unss") suggested that both effects could be explained by one process: arousal.

The presence of other people, said Zajonc (1965), increases a person's general level of arousal or motivation. Why? One reason is that being watched by others increases our sense of being evaluated, producing worry that in turn increases emotional arousal (Uziel, 2007). Arousal increases the tendency to display our most *dominant* behaviors—the ones we know best. Engaging in those dominant behaviors can sometime help our performance and sometimes hinder it. If you are performing an easy, familiar task, such as riding a bike, the increased arousal caused by the presence of others should allow you to ride even faster than normal. But if the task is hard or unfamiliar—such as trying new dance steps or playing a piano piece you just learned—the most dominant responses may be incorrect and cause your performance to suffer. In other words, the impact of other people on performance depends on whether the task is easy or difficult.

The presence of others may affect performance in other ways as well. For example, having an audience may distract us from the task at hand or cause us to focus on only one part of it, thus impairing performance (Aiello & Douthitt, 2001).

What if a person is not merely in the presence of others but is actually working on a task with them? In these situations, people typically exert less effort than they do when performing alone, a phenomenon called **social loafing** (Liden et al., 2004).

social facilitation A phenomenon in which the presence of others improves a person's performance

social interference A reduction in performance due to the presence of other people.

social loafing Exerting less effort when performing a group task than when performing the same task alone.

Social Facilitation

Top athletes like Serena Williams, shown here winning the 2010 women's singles championship at Wimbledon, are able to perform at their best even though large crowds are present. In fact, the crowds probably help them do well, because the presence of others tends to increase arousal, which enhances the performance of familiar and well-learned skills, such as tennis strokes. However, arousal created by an audience tends to interfere with the performance of unfamiliar and poorly developed skills. This is one reason that professional athletes who show flawless grace in front of thousands of fans are likely to freeze up or blow their lines in front of a small production crew when trying for the first time to tape a TV ad or a public service announcement.

© Kirsty Wigglesworth/AP Photo

Whether the task is pulling on a rope, clapping as loudly as possible, trying to solve puzzles, or working together on a class project, people tend to work harder when performing alone than with others (Price, Harrison, & Gavin, 2006; van Dick et al., 2009). There are at least three reasons behind this social loafing phenomenon. First, it is usually much harder to evaluate the performance of individuals when they are working as part of a group. As a result, it is simply easier to succeed at loafing when in a group. Second, rewards may come to a group whether or not every member exerts maximum effort. Third, a group's rewards are usually divided equally among its members rather than according to individual effort (Hoigaard & Ingvaldesen, 2006; Pearsall, Christian, & Ellis, 2010).

In North American and other Western countries, social loafing can be seen in all kinds of groups, from volunteer committees to search parties. Because social loafing can reduce productivity in business situations, it is important for managers to counteract it by finding ways to evaluate the efforts of every individual in a work group, not just the overall output of the team. Social loafing also tends to be reduced when members like and identify with the group (Hoigaard, Säfvenbom, & Tonnessen, 2006) and when harder-working members express their disapproval of social loafers (Barclay, 2006).

Social loafing is much less common in Eastern cultures, such as those of China and Japan. In fact, in collectivist cultures, working in a group usually produces *social striving*—defined as greater individual effort when working in a group (Matsumoto, 2000). This difference in the effects of group membership on individual efforts probably reflects the value that collectivist cultures place on coordinated and cooperative group activities.

Conformity and Compliance

Suppose that you are with three of your friends. One says that Franklin Roosevelt was the greatest president in the history of the United States. You think that the greatest president was Abraham Lincoln, but before you can say anything, another friend agrees that it was Roosevelt, and then the other one does as well. What would you do? Disagree with all three? Maintain your opinion but keep quiet? Change your mind?

Mass Conformity

The faithful who gather at Mecca, at the Vatican, and at other holy places around the world exemplify the power of religion and other social forces to produce conformity to group norms.

When people change their behavior or beliefs to match those of other members of a group, they are said to conform. **Conformity** occurs as a result of group pressure, real or imagined (Hogg, 2010). You have probably experienced such group pressure when everyone around you stood to applaud a performance you thought was not that great. You may have conformed by standing as well, though no one told you to do so. The group's behavior created a silent but influential pressure to follow suit. **Compliance**, in contrast, occurs when people adjust their behavior because of a request. The request can be clear and *explicit,* as when someone says, "Could you do me a favor?" or subtle and *implicit,* as when someone simply looks at you in a way that lets you know the person needs a favor.

The Role of Social Norms

Conformity and compliance are usually generated by spoken or unspoken social norms. In a classic experiment, Muzafer Sherif (1937) charted the formation of a group norm by taking advantage of a perceptual illusion, called the *autokinetic effect.* In this illusion, a stationary point of light in a pitch-dark room appears to move. Estimates of the amount of movement tend to stay the same over time—if an observer is alone. But when Sherif tested people in groups, asking each person to say aloud how far the light moved on repeated trials, their estimates tended to converge. They had established a group norm. Even more important, when the individuals from the group were later tested alone, they continued to be influenced by this social norm.

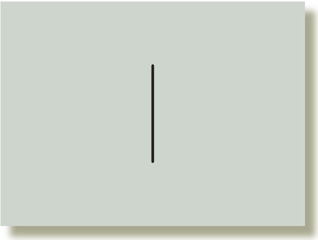
In another classic experiment, Solomon Asch (1956) examined how people would respond when they faced a social norm that already existed but was obviously wrong. The participants in this experiment saw a standard line like the one in part A of Figure 18.1; then they saw a display like that in part B. Their task was to pick out the line in the display that was the same length as the one they had first been shown.

Each participant performed this task in a small group of people who posed as fellow participants but who were actually the experimenter's assistants. There were two conditions. In the control condition, the real participant responded first. In the experimental condition, the participant did not respond until after the assistants did. The assistants chose the correct response on six trials, but on the other twelve trials,

conformity Changing one's behavior or beliefs to match those of others, generally as a result of real or imagined, though unspoken, group pressure.

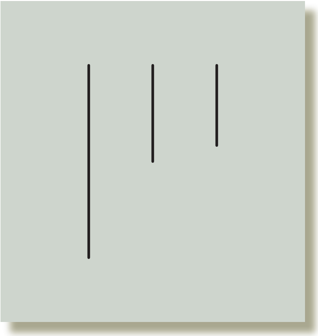
compliance Adjusting one's behavior because of an explicit or implicit request.

they all gave the same obviously incorrect response. So on twelve trials, each participant was confronted with a “social reality” created by a group norm that conflicted with the physical reality created by what the person could clearly see. Only 5 percent of the participants in the control condition ever made a mistake on this easy task. However, among participants who heard the assistants’ responses before giving their own, about 70 percent made at least one error by conforming to the group norm. An analysis of 133 studies conducted in seventeen countries reveals that conformity in Asch-type situations has declined somewhat in the United States since the 1950s, but it still occurs. It is especially likely in collectivist cultures, in which conformity to group norms is emphasized (Cialdini et al., 2001).



Standard line

(A)



Test lines

(B)

FIGURE 18.1
Stimulus Lines for Conformity Studies

TRY THIS Participants in Asch’s experiments saw a new set of lines like these on each trial. The middle line in part B matches the one in part A, but when several of Asch’s assistants chose an incorrect line, so did many of the participants. Try re-creating this experiment with four friends. Secretly ask three of them to choose the line on the left when you show this drawing; then see if the fourth person conforms to the group norm. If not, do you think it was something about the person, the length of the incorrect line chosen, or both that led to nonconformity? Would conformity be more likely if the first three people were to choose the line on the right? (The text provides more information about this possibility.)

Sources: Asch (1955).

Pressure to conform can even affect reports about personal experiences. In one study that used a procedure similar to Asch’s, participants were shown a number of objects. Later the same objects were shown again, along with some new ones, and the participants were asked to say whether they had seen each object in the previous display. When tested alone, the participants’ memories were quite accurate, but hearing another person’s opinion about which objects had or had not been shown before strongly affected their memory of which objects they had seen (Hoffman et al., 2001).

Why Do People Conform?

Why did so many people in Asch’s experiment and others like it give incorrect responses when they were capable of near-perfect performance? One possibility is that they displayed public conformity, giving an answer they did not believe simply because it was the socially desirable thing to do. Another possibility is that they experienced *private acceptance:* Perhaps the participants used other people’s responses as legitimate evidence about reality, were convinced that their own perceptions were wrong, and actually changed their minds. Morton Deutsch and Harold Gerard (1955) reasoned that if conformity disappeared when people gave their responses without identifying themselves, Asch’s findings must reflect public conformity, not private acceptance. Actually, conformity does decrease when people respond anonymously instead of publicly, but it doesn’t disappear (Deutsch & Gerard, 1955). So people sometimes say things in public that they don’t believe, but hearing other people’s responses also influences their private beliefs (Moscovici, 1985).

Why are group norms so powerful? Research suggests three influential factors (Kenrick, Neuberg, & Cialdini, 2010). First, people want to be correct, and social norms provide information about what is right and wrong. Second, people want others to like and accept them, so they may seek favor by conforming to the social norms that those others have established (Hewlin & Faison, 2009).Third, conforming to group norms may increase a person’s sense of self-worth, especially if the group is valued or prestigious (Cialdini & Goldstein, 2004). The process may occur without our awareness (Lakin & Chartrand, 2003). For example, observations of interviews by Larry King, the recently retired television talk show host, revealed that he tended to imitate the speech patterns of high-status guests but not low-status ones (Gregory & Webster, 1996).

Finally, social norms influence the distribution of social rewards and punishments (Cialdini, 1995). From childhood on, people in many cultures learn that going along with group norms is good and earns rewards. (These positive outcomes presumably help compensate for not always being able to say or do exactly what we please.) People also learn that breaking a social norm may bring punishments ranging from scoldings for small transgressions to imprisonment for violation of norms that have been translated into laws.

When Do People Conform?

People do not always conform to social influence. In the original Asch studies, for example, nearly 30 percent of the participants did not go along with the research assistants’ obviously incorrect judgments. Countless experiments have probed the question of what combinations of people and circumstances do and do not lead to conformity.

Ambiguity of the Situation *Ambiguity,* or uncertainty, is very important in determining how much conformity will occur. As the physical reality of a situation becomes less certain, people rely more and more on others' opinions, and conformity to a group norm becomes increasingly likely (Cialdini & Goldstein, 2004).

TRY THIS

You can demonstrate this aspect of conformity on any street corner. First, create an ambiguous situation by having several people look at the sky or the top of a building. When passersby ask what is going on, be sure everyone excitedly reports seeing something interesting but fleeting—perhaps a faint light or a tiny, shiny object. If you are especially successful, conforming newcomers will begin persuading other passersby that there is something fascinating to be seen.

Unanimity and Size of the Majority If ambiguity contributes so much to conformity, why did so many of Asch's participants conform to a judgment that was so clearly wrong? The answer has to do with the *unanimous* nature of the group's judgment and the number of people expressing it. Specifically, people experience great pressure to conform as long as the majority is unanimous. If even one other person in the group disagrees with the majority view, conformity drops greatly. When Asch (1951) arranged for just one assistant to disagree with the others, fewer than 10 percent of the real participants conformed. Once unanimity is broken, it becomes much easier to disagree with the majority, even if the other nonconformist does not agree with the person's own view (Turner, 1991).

Conformity also depends on the *size of the majority.* Asch (1955) demonstrated this phenomenon by varying the number of assistants in the group from one to fifteen. Conformity to incorrect social norms grew as the number of people in the group increased. But most of the growth in conformity occurred as the size of the majority rose from one to about three or four members. Further additions had little effect. Several years after Asch's research, Bibb Latané (pronounced "lat-uh-NAY") sought to explain this phenomenon with his *social impact theory.* This theory holds that a group's impact on an individual depends not only on group size but also on how important and close the group is to the person. And according to Latané (1981), the impact of increasing the size of a majority depends on how big the majority was originally. Increasing a majority from, say, two to three will have much more impact than increasing it from, say, sixty to sixty-one. The reason is that the increase from sixty to sixty-one is psychologically much smaller than the change from two to three; it attracts far less notice in relative terms. Does this explanation sound familiar? The principles underlying it are similar to those of Weber's law, which, as described in the chapter on perception, governs our experience of changes in brightness, weight, and other physical stimuli.

Minority Influence Conformity can also result from *minority influence,* by which a minority in a group influences the behavior or beliefs of a majority (Hogg, 2010). This phenomenon is less common than majority influence, but minorities can be influential in producing private acceptance of new ideas, especially when members of the minority agree with one another and persist in their views (Hogg, 2010; Mucchi-Faina & Pagliaro, 2008). Minority-influenced change often takes place slowly and is most likely to occur when those holding a minority view are perceived as loyal members of the group (Crano & Seyranian, 2009).

Gender Early research on conformity suggested that women conform more than men. However, the tasks used in those experiments were often more familiar to men than to women. This fact is important because people are especially likely to conform when they are faced with an unfamiliar situation (Cialdini & Goldstein, 2004). Those studies also usually required people to make their responses aloud so that everyone knew if they had conformed or not. When the experimental tasks are equally familiar to both genders and when people can make their responses privately, no male-female differences in conformity are found. Accordingly, it has been suggested that gender differences in public conformity are based not on a genuine difference in reactions to social pressure but rather on men's desire to be seen as strong and independent and women's desire to be seen as cooperative (Hogg, 2010; Kenrick, Neuberg, & Cialdini, 2010).

APPLYING PSYCHOLOGY Have you ever been asked to sign a petition in favor of a political, social, or economic cause? Supporters of these causes know that people who comply with this small request are the best ones to contact later with requests to do more. Complying with larger requests is made more likely because it is consistent with the signer's initial commitment to the cause. If you have ever been contacted after signing a petition, did you agree to donate money or perhaps become a volunteer?

Creating Compliance

In the conformity experiments we have described, the participants experienced psychological pressure to conform to the views or actions of others, even though no one specifically asked them to do so. In contrast, *compliance* involves changing what you say or do as the result of a request.

How is compliance brought about? Many people believe that the direct approach is always best: If you want something, ask for it. But salespeople, political strategists, social psychologists, and other experts have learned that often the best way to get something is to ask for something else. Three examples of this strategy are the foot-in-the-door technique, the door-in-the-face technique, and the low-ball technique.

The *foot-in-the-door technique* works by getting a person to agree to a small request and then gradually presenting larger ones. (The name refers to a fact that all door-to-door salespeople know: If you can get a potential customer to let you in the door, you have a much better chance of making a sale.) In the original experiment on this technique, homeowners were asked to do one of two things. Some were asked to allow a large, unattractive "Drive Carefully" sign to be placed on their front lawns. Approximately 17 percent of the people approached in this way complied with the request. In the foot-in-the-door condition, however, homeowners were first asked only to sign a petition supporting legislation aimed at reducing traffic accidents. Several weeks later, when a different person asked these same people to put the "Drive Carefully" sign on their lawns, 55 percent of them complied (Freedman & Fraser, 1966).

Why should the granting of a small favor lead to the granting of a larger one? First, people are usually far more likely to comply with a request that costs little in time, money, effort, or inconvenience. Second, complying with a small request makes people think of themselves as being committed to the cause or issue involved. This change occurs through the processes of self-perception and cognitive dissonance discussed in the chapter on social cognition (Kassin, Fein, & Markus, 2010). In the study just described, participants who signed the petition may have thought, "I signed, so I must care enough about traffic safety to be willing to do something about it." Compliance with the higher-cost request (displaying the "drive safely" sign) then became more likely because it was consistent with these people's self-perceptions and past actions (Burger & Caldwell, 2003).

The foot-in-the-door technique can be quite effective. In one study, women were significantly more likely to agree to have a drink with a man they had just met if they had first agreed to a smaller favor, such as giving him directions to an address he was seeking (Guéguen et al., 2008). In some business strategies, the foot in the door can come as a request that potential customers merely provide a phone number or an e-mail address. The request to buy something comes later. Other companies offer a small gift or "door opener," as salespeople call it. Acceptance of the gift not only allows a foot in the door but may also activate the reciprocity norm: Many people who get something free of charge feel obligated to reciprocate by buying something—especially if the request to do so is delayed for a while (Cialdini, 2007; Guadagno et al., 2001).

The *door-in-the-face technique* offers a second way of obtaining compliance (Turner et al., 2007). This strategy begins with a request for a favor that is likely to be denied (as when a door is slammed in a salesperson's face). The person making the request then concedes that asking for the initial favor was excessive and substitutes a lesser alternative—which was what the person really wanted in the first place. Because the person appears willing to compromise and because the new request seems modest in comparison with the first one, it is more likely to be granted than if it had been made at the outset. Here again, compliance appears to be due partly to activation of the reciprocity

"OK, OK, I'll Be Home by One!"

APPLYING PSYCHOLOGY The door-in-the-face technique is sometimes used successfully by teenagers to influence parents to comply with many kinds of requests. After asking to stay out overnight, a youngster whose curfew is normally 11:00 P.M. might be allowed to stay out until 1:00 A.M.—a "compromise" that was actually the original goal.

© Ariel Skelley/Corbis

norm: This person is making a concession to me, so I should really make a concession in return. The door-in-the-face technique often lies at the heart of the bargaining that takes place among political groups and between labor and management (Ginges et al., 2007).

A third way of gaining compliance, called the *low-ball technique,* is commonly used by car dealers and other salespeople. The first step in this strategy is to obtain a person's oral commitment to do something, such as to purchase a car at a certain price. Once this commitment is made, the cost of fulfilling it is increased, often because of an "error" in calculating the car's price. Why do buyers end up paying much more than originally planned for lowballed items? Apparently, once people say they will do something, they feel obligated to follow through, especially when the commitment was made in public and when the person who obtained the initial commitment is also the one who tells the buyer about the price increase (Burger & Cornelius, 2003). In other words, as described in relation to cognitive dissonance theory in the chapter on social cognition, people like to be consistent in their words and deeds. In this case, it appears that people try to maintain a positive self-image by acting in accordance with their previously stated intention, even though it may cost them a great deal to do so.

Obedience

Compliance involves a change in behavior in response to a request. In the case of **obedience**, the behavior change comes in response to a *demand* from an authority figure (Kenrick, Neuberg, & Cialdini, 2010). In the 1960s, Stanley Milgram developed a laboratory procedure at Yale University to study obedience. In his first experiment, he used newspaper ads to recruit forty male volunteers between the ages of 20 and 50. Among the participants were professionals, white-collar businessmen, and unskilled workers (Milgram, 1963).

obedience Changing behavior in response to a demand from an authority figure.

Imagine that you are one of the people who answered the ad. When you arrive for the experiment, you join a 50-year-old gentleman who has also volunteered and has been scheduled for the same session. The experimenter explains that the purpose of the experiment is to examine the effects of punishment on learning. One of you—the "teacher"—will help the "learner" remember a list of words by administering an electrical shock whenever he makes a mistake. Then the experimenter turns to you and asks you to draw one of two cards out of a hat. Your card says "Teacher." You think to yourself that this must be your lucky day.

Now the learner is taken into another room and strapped into a chair. Electrodes are attached to his arms. Meanwhile, you are shown a shock generator featuring thirty switches. The experimenter explains that the switch on the far left administers a mild, 15-volt shock and that each succeeding switch increases the shock by 15 volts. The switch on the far right delivers 450 volts. The far-left section of the shock generator is labeled "slight shock." Looking across the panel, you see "moderate shock," "very strong shock," and at the far right, "danger—severe shock." The last two switches are ominously labeled "XXX." The experimenter explains that you, the teacher, will begin by reading a list of word pairs to the learner. Then you will go through the list again, presenting just one word of each pair. It is the learner's task to say which word went with it. After the first mistake, you are to throw the switch to deliver 15 volts of shock. Each time the learner makes another mistake, you are to increase the shock by 15 volts.

You begin, following the experimenter's instructions. But after the learner makes his fifth mistake and you throw the switch to give him 75 volts, you hear a loud moan. At 90 volts, the learner cries out in pain. At 150 volts, he screams and asks to be let out of the experiment. You look to the experimenter, who says, "Proceed with the next word."

No shock was actually delivered in Milgram's experiments. The learner was always an employee of the experimenter, and the moans and other sounds of pain came from a prerecorded tape. But you don't know that. What would you do in this situation? Suppose that you continue and eventually deliver 180 volts. At that point, the learner screams that he cannot stand the pain any longer and starts banging on the wall. The experimenter says, "You have no other choice; you must go on." Would you continue? Would you keep going even when the learner begged to be let out of the experiment and then fell silent? Would you administer 450 volts of potentially deadly shock to a perfect stranger just because an experimenter demanded that you do so?

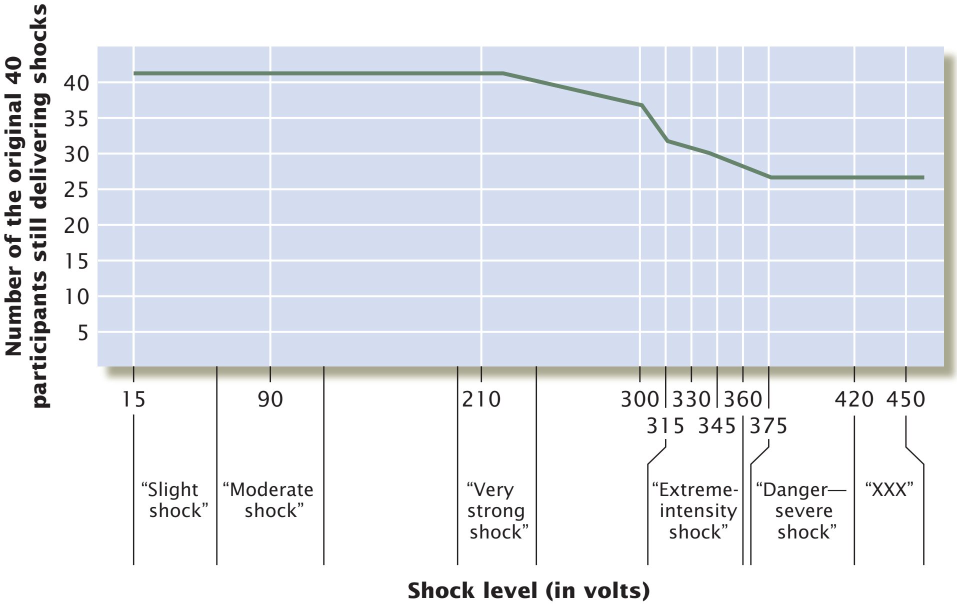
Figure 18.2 shows that only five of the forty participants in Milgram's experiment stopped before 300 volts, and twenty-six participants (65 percent) went all the way to the 450-volt level. The decision to continue was difficult and stressful for the participants. Many protested repeatedly, but each time the experimenter told them

FIGURE 18.2

Results of Milgram's Obedience Experiment

When Stanley Milgram asked a group of undergraduates and a group of psychiatrists to predict how participants in his experiment would respond, they estimated that no more than 2 percent would go all the way to 450 volts. In fact, 65 percent of the participants did so. What do you think you would have done in this situation?

Source: From S. Milgram. "Behavioral Study of Obedience." *Journal of Abnormal and Social Psychology,* 67, pp. 371–378. Reprinted by permission.



to continue, they did so. Here is a partial transcript of what a typical participant said (Milgram, 1974, p. 74):

> [*After throwing the 180-volt switch*] He can't stand it. I'm not going to kill that man in there. Do you hear him hollering? He's hollering. He can't stand it. What if something happens to him? I'm not going to get that man sick in there. He's hollering in there. Do you know what I mean? I mean, I refuse to take responsibility. He's getting hurt in there.… Too many [word pairs] left here. Geez, if he gets them wrong. There are too many of them left. I mean, who is going to take responsibility if anything happens to that gentleman?…
>
> [*After the experimenter accepts responsibility*] All right.…
>
> [*After administering 240 volts*] Oh, no, you mean I've got to keep going up the scale? No, sir, I'm not going to kill that man. I'm not going to give him 450 volts.…
>
> [*After the experimenter says, "The experiment requires that you go on"*] I know it does, but that man is hollering in there, sir.

This participant administered shocks up to 450 volts.

Factors Affecting Obedience

Milgram had not expected so many people to deliver such apparently intense shocks. Was there something about his procedure that produced this high level of obedience? To find out, Milgram and other researchers varied the original procedure in a number of ways. The overall level of obedience to an authority figure was usually quite high, but the degree of obedience was affected by several factors.

Experimenter Status and Prestige In Milgram's original study, the experimenter's status and prestige as a Yale University professor created two kinds of social power that affected the participants. The first was *expert power,* which is the ability to influence people because they assume that the person in power is a knowledgeable and responsible expert. The second was *legitimate power,* which is the ability to influence people because they assume that the person in power has the right or legitimate authority to tell them what to do (Blass, 2009).

To test the effects of reduced status and prestige, Milgram rented an office in a rundown building in Bridgeport, Connecticut. He then placed a newspaper ad for people to participate in research sponsored by a private firm. There was no mention of Yale. In all other ways, the experimental procedure was identical to the original. Under these less impressive circumstances, the level of obedience dropped, but not as much as you might expect; 48 percent of the participants continued to the maximum level of shock, compared to 65 percent in the original study. Milgram concluded that people still would obey instructions that could cause great harm to another even if the authority figure was not associated with a prestigious institution. Evidently, people's willingness to follow orders from an authority operates somewhat independently of the setting in which the orders are given.

The Behavior of Other People To study how the behavior of fellow participants might affect obedience, Milgram (1965) created a situation in which there were apparently three teachers. Teacher 1 (in reality, a research assistant) read the words to the learner. Teacher 2 (another research assistant) stated whether or not the learner's response was correct. Teacher 3 (the actual participant) was to deliver a shock when mistakes were made. At 150 volts, when the learner began to complain that the shock was too painful, Teacher 1 said he would not participate any longer and left the room. The experimenter asked him to come back, but he refused. The experimenter then instructed Teachers 2 and 3 to continue by themselves. The experiment went on for several more trials. However, at 210 volts, Teacher 2 said that the learner was suffering too much and refused to participate further. The experimenter then told Teacher 3

Proximity and Obedience

Milgram's research suggested that the close physical proximity of an authority figure is one of several factors that can enhance obedience to authority (Rada & Rogers, 1973). This proximity principle is employed in the military, where no one is ever far away from the authority of a higher-ranking person.

© John Chiasson/Getty Images

(the actual participant) to continue the procedure. In this case, only 10 percent of the participants (compared to 65 percent in the original study) continued to deliver shocks all the way up to 450 volts. In other words, as research on conformity would suggest, the presence of others who disobey appears to be the most powerful factor in reducing obedience.

The Behavior of the Learner A reanalysis of data from Milgram's obedience studies (Packer, 2008) found that although the learner's increasingly intense expressions of pain did not affect whether the participants disobeyed the experimenter, the learner's request to be released from the experiment did affect disobedience. In fact, among those participants who refused to continue to shock the learner, almost 37 percent of them disobeyed at the 150-volt level, which was when the learner first said he wanted to be released from the experiment. So it appears that perceiving a victim's pain does not reduce obedience to authority but being reminded of a victim's right to be released from the experiment does.

Personality Characteristics Were the participants in Milgram's original experiment heartless creatures who would have given strong shocks even if there had been no pressure on them to do so? Quite the opposite; most of them were nice people who were influenced by experimental situations to behave in apparently antisocial ways. In a later demonstration of the same phenomenon, college students playing the role of prison guards behaved with aggressive heartlessness toward other students who were playing the role of prisoners (Zimbardo, 1973). A more recent illustration of this phenomenon occurred among certain groups of soldiers who were assigned to guard or interrogate prisoners in Afghanistan and Iraq.

Still, not everyone is obedient to authority. For example, people high in *authoritarianism* (a characteristic discussed in the chapter on social cognition) are more likely than others to comply with an experimenter's request to shock the learner (Blass, 1991). Support for this idea comes from data suggesting that German soldiers who obeyed orders to kill Jews during World War II were higher on authoritarianism than other German men of the same age and background (Steiner & Fahrenberg, 2000). In contrast, a recent study that repeated Milgram's experimental procedures (Burger, 2009) found that the participants who were less likely to obey orders to harm the learner were also the ones who were concerned about others and predisposed to have *empathy*—that is, to understand or experience another person's emotional state (Davis, 1994).

Evaluating Milgram's Studies

How relevant are Milgram's 1960s studies in today's world? Consider this fact: The U.S. Federal Aviation Administration attributes some commercial airline accidents to a phenomenon it calls "captainitis." This phenomenon occurs when the captain of an aircraft makes an obvious error but the copilot is unwilling to challenge the captain's authority by pointing out the mistake. As a result, planes have crashed and people have died (Kanki & Foushee, 1990). Obedience to authority may also have operated during the World Trade Center attack on 9/11, when some people who had started for the exits returned to their offices after hearing an ill-advised public address announcement telling them to do so. Most of these people died as a result. Similar kinds of obedience have been observed in experiments conducted in many countries, from Europe to the Middle East, with female as well as male participants (Burger, 2009). In short, people appear to be as likely to obey orders today as they were when Milgram conducted his research (Blass, 2009). Nevertheless, many aspects of Milgram's work still provoke debate. (For a summary of Milgram's results, plus those of studies on conformity and compliance, see "In Review: Types of Social Influence.")

"May I Take Your Order?"

In February 2004, the managers of four fast-food restaurants in Boston received calls from someone claiming to be a police detective on the trail of a robbery suspect. The caller said that the suspect might be one of the restaurant's employees and told the managers to strip-search all of them for evidence of guilt. The calls turned out to be hoaxes, but every manager obeyed this bizarre order, apparently because it seemed to come from a legitimate authority. In two similar cases, residents of a special-needs school were given unnecessary electric shock treatments on telephoned orders from a hoaxer, and hospital nurses obeyed medical treatment orders given by a teenager who claimed to be a doctor (Kenrick, Neuberg, & Cialdini, 2010; "Officials Investigating," 2007).

LINKAGES Is it ethical to deceive people in order to learn about their social behavior? (a link to Research in Psychology, p. 57)

Questions About the Ethics of Milgram's Research Although the "learners" in Milgram's experiment suffered no discomfort, the participants did. Milgram (1963) saw participants "sweat, stutter, tremble, groan, bite their lips, and dig their fingernails into their flesh" (p. 375). Against the potential harm inflicted by Milgram's experiments stand the potential gains. For example, students and others who learn about Milgram's work often take his findings into account when deciding whether to be obedient in social situations (Sherman, 1980). But even if social value has come from Milgram's studies, the question remains: Was it ethical for Milgram to treat his participants as he did?

In the years before his death in 1984, Milgram defended his experiments (e.g., Milgram, 1977). He argued that his debriefing of the participants after the experiment prevented any lasting harm. For example, to demonstrate that their behavior was not unusual, Milgram told participants that most people went all the way to the 450-volt level. He also explained that the learner did not experience any shock; to confirm this fact, the learner then came in and had a friendly chat with each participant. On a later questionnaire, 84 percent of the participants said that they had learned something important about themselves and that the experience had been worthwhile. Milgram argued, therefore, that the experience was actually a positive one. Still, the committees charged with protecting human participants in research today would be unlikely to approve Milgram's experiments as they were originally done. Fortunately, less controversial ways to study obedience have been developed (Elms, 2009).

Questions About the Meaning of Milgram's Research Do Milgram's dramatic results mean that most people are putty in the hands of authority figures and that most of us would blindly follow inhumane orders from our leaders? Some critics have argued that Milgram's results cannot be interpreted in this way because his participants knew they were in an experiment and may simply have been playing a cooperative role. If so, the social influence processes identified in his studies may not explain obedience in the real world today.

Most psychologists believe, however, that Milgram not only demonstrated the power of obedience to authority but also revealed—or perhaps confirmed—a basic truth about human behavior: that under certain circumstances, human beings are capable of unspeakable acts of brutality toward other humans (Benjamin & Simpson, 2009). Sadly, examples abound. And one of the most horrifying aspects of human inhumanity—whether the Nazis' campaign of genocide against Jews in the 1930s and 1940s or the campaigns of terror under way today—is that the perpetrators are not necessarily demented, sadistic fiends. Most of them are, in many respects, "normal" people who have been influenced by economic and political situations and

A Shocking Game Show

On March 17, 2010, a French television station aired *The Extreme Zone,* a quiz show that allowed contestants—with the enthusiastic support of a live studio audience—to punish another contestant's incorrect answers by giving him increasingly severe electric shocks. Neither the contestants nor the audience knew that the show was actually a documentary designed to test people's willingness to harm others. The actor who played the punished contestant was never really shocked, but as shown in this photo, his fake suffering was quite convincing. Though he begged them to stop, 80 percent of the contestants—more than in Milgram's original obedience experiment—delivered the maximum shock. These results provided dramatic evidence that potentially deadly aggression can be triggered by many social influences, including competition and peer encouragement.

IN REVIEW Types of Social Influence

Type	Definition	Key Findings
Conformity	A change in behavior or beliefs to match those of others	In cases of ambiguity, people develop a group norm and then adhere to it. Conformity occurs because people want to be right, because they want to be liked by others, and because conformity to group norms is usually rewarded. Conformity usually increases with the ambiguity of the situation, as well as with the unanimity and psychological size of the majority.
Compliance	A change in what is said or done as the result of a request	Compliance increases with the foot-in-the-door technique, which begins with a small request and works up to a larger one. The door-in-the-face technique can be used too. After making a large request that is denied, the person substitutes the less extreme alternative that was desired all along. The low-ball technique also elicits compliance. A person first obtains an oral commitment for something and then claims that only a higher-cost version of the original request will suffice.
Obedience	A change in behavior in response to an explicit demand, typically from an authority figure	People may inflict great harm on others when an authority demands that they do so. Even though people obey orders to harm another person, they often agonize over the decision. People are most likely to disobey orders to harm someone when they see another person disobey such orders.

1. Joining the end of a ticket line is an example of ____________, whereas forming two lines when a theater employee requests it is an example of ____________.

2. Seeing someone disobey a questionable order makes people ____________ likely to obey the order themselves.

3. Pricing your used car for more than you expect to get and then agreeing to reduce it to make a sale is an example of the ____________ approach to gaining compliance.

the persuasive power of their leaders to behave in a demented and fiendish manner (Moghaddam, 2005; Zimbardo, 2008).

In short, inhumanity can occur even without pressure for obedience. For example, a good deal of people's aggressiveness toward other people appears to come from within. Let's now consider human aggressiveness and some of the circumstances that influence its expression.

Aggression

Aggression is an action intended to harm another person (Bushman & Huesmann, 2010). It is all too common. Nearly 1.4 million violent crimes are committed each year in the United States, including nearly 90,000 rapes and about 17,000 murders (Federal Bureau of Investigation, 2008). In fact, homicide is the second leading cause of death for people in the United States between the ages of 15 and 24 (Heron, 2007). One of the most disturbing aspects of these figures is that about 85 percent of all murder victims knew their assailants, and over 70 percent of rapists were romantic partners, friends, relatives, or acquaintances of their victims (U.S. Department of Justice, 2007). Further, about one-third of married people in the United States, and a significant proportion of dating couples, display aggression toward each other that ranges from pushing, shoving, and slapping to beatings and the threatened or actual use of weapons (Cornelius & Resseguie, 2007; Durose et al., 2005).

Why Are People Aggressive?

Sigmund Freud proposed that aggression is an instinctive biological urge that builds up in everyone and must be released. Sometimes, he said, the release takes the form of physical or verbal abuse against others. At other times, the aggressive impulse is turned inward and leads to suicide or other self-damaging acts.

LINKAGES What makes some people so aggressive? (a link to Introducing Psychology, p. 20)

A somewhat more complicated view is offered by evolutionary psychologists. As discussed in the introductory chapter, these psychologists believe that human social behavior is related to our evolutionary heritage. From this perspective, aggression is thought to have helped prehistoric people compete for mates, resulting in the survival of their genes in the next generation. Through the principles of natural selection, then, aggressive tendencies were passed on through successive generations (Ferguson & Beaver, 2009).

Evolutionary theories of the origins of aggression are popular, but even evolutionary theorists realize that nature alone cannot fully account for aggression. Nurture, in the form of environmental factors, also plays a large role in determining when and why people are aggressive. We know this partly because there are large differences in aggression from culture to culture. The murder rate in Colombia, for example, is more than fifteen times as high as in the United States, and the U.S. murder rate is almost twice as high as in either Canada or the United Kingdom (United Nations Office on Drugs and Crime, 2007). These data suggest that even if aggressive *impulses* are universal, the emergence of aggressive *behavior* reflects an interplay of nature and nurture (Bushman & Huesmann, 2010). No equation can predict when people will be aggressive, but years of research have revealed a number of important biological, learning, and environmental factors that combine in various ways to produce aggression in various situations.

Genetic and Biological Mechanisms There is strong evidence for hereditary influences on aggression, especially in animals (Bushman & Huesmann, 2010). In one study, the most aggressive members of a large group of mice were interbred. Then the most aggressive of their offspring were also interbred. After this procedure was followed for twenty-five generations, the resulting animals would immediately attack

aggression An act that is intended to cause harm to another person.

any mouse put in their cage. Continuous inbreeding of the least aggressive members of the original group produced animals that were so docile that they would refuse to fight even when attacked (Lagerspetz & Lagerspetz, 1983). Research on human twins reared together or apart suggests that there is a genetic component to aggression in people as well (Vierikko et al., 2006). However, other research suggests that people do not necessarily inherit the tendency to be aggressive; instead, they may inherit certain temperaments, such as impulsiveness or emotional oversensitivity in social situations, that in turn make aggression more likely (Alia-Klein et al., 2009; Eisenberger et al., 2007; Hennig et al., 2005).

Several parts of the brain influence aggression (Anderson & Bushman, 2002a). One is the limbic system, which includes the amygdala, the hypothalamus, and related areas (see Figure 3.12 in the chapter on biological aspects of psychology). Damage to these structures may produce *defensive aggression,* which includes heightened aggressiveness to stimuli that are not usually threatening or a decrease in the responses that normally inhibit aggression (Coccaro, 1989; Siever, 2008). The cerebral cortex may also be involved in aggression (e.g., Séguin & Zelazo, 2005; see Figure 3.15). For example, one study found that the prefrontal area of the cortex metabolized glucose significantly more slowly in murderers than in other people (Raine, Brennan, & Mednick, 1994).

Hormones such as *testosterone*—the male hormone that is present in both sexes—may also play an important role in aggression (Bushman & Huesmann, 2010). Experiments have shown that aggressive behavior increases or decreases dramatically with the level of testosterone in the human bloodstream (Klinesmith, Kasser, & McAndrew, 2006). Among criminals, those who commit violent crimes have higher levels of testosterone than those whose crimes are nonviolent. And among murderers, those with higher levels of testosterone are more likely than others to have planned their crimes before committing them (Dabbs, Riad, & Chance, 2001).

Testosterone may have its most significant and durable influence not so much through its day-to-day variations as through its impact on early brain development. One natural test of this hypothesis occurred when pregnant women were given testosterone in an attempt to prevent miscarriages. Accordingly, their children were exposed to high doses of testosterone during prenatal development. Figure 18.3 shows that these children grew up to be more aggressive than their same-sex siblings who were not exposed to testosterone during prenatal development (Reinisch, Ziemba-Davis, & Sanders, 1991). Another study found that girls who had been prenatally exposed to elevated levels of testosterone by virtue of having shared the womb with a male twin were more aggressive than girls who had a female twin (Cohen-Bendahan et al., 2005).

More recent research with both animals and humans has linked lower levels of the neurotransmitter serotonin with higher levels of impulsive aggression (Carver, Johnson, & Joormann, 2008). In one study, research participants who were randomly selected to receive a serotonin-raising drug behaved much less aggressively in a competitive game than those whose serotonin remained unchanged (Berman et al., 2009). Similarly, people who commit impulsive violent crimes tend to have lower levels of serotonin than those whose crimes are premeditated (Bushman & Huesmann, 2010).

Drugs that alter central nervous system functioning can also affect the likelihood that a person will act aggressively. Alcohol, for example, can substantially increase some people's aggressiveness (Giancola et al., 2010). Canadian researchers have found that in almost 70 percent of the acts of aggression they studied, the aggressors had been drinking alcohol. And the more alcohol the aggressors consumed, the more aggressive they were (Wells, Graham, & West, 2000). No one knows exactly why alcohol increases aggression, but there is no doubt that many people associate drinking with both aggressive thoughts and aggressive actions (Bartholow & Heinz, 2006). In fact, people may become more aggressive after drinking a nonalcoholic beverage that they *think* contains alcohol (Bègue et al., 2009). As described in the consciousness chapter, this association may result in part from observing the drunken aggressiveness that is common in many cultures.

Research on the effects of other drugs on aggression has produced some surprising findings. One might expect, for example, that using stimulants would increase aggressiveness and that taking tranquilizers would reduce it, but the opposite appears to be true. Whereas amphetamine stimulants do not usually make people more aggressive, opiates (e.g., heroin and morphine) and some tranquilizers may do so (Taylor & Hulsizer, 1998). It is not clear why heroin users are more likely than amphetamine users to be aggressive. Some analysts have suggested that heroin addicts' aggression reflects their desperate need to get money to buy more drugs. But if this were so, we should also see increased aggression among people who are addicted to amphetamines and cocaine—because these addictions, too, are very expensive. Further, opiates increase people's aggressiveness even in controlled laboratory settings (Taylor & Hulsizer, 1998), suggesting that these drugs have biochemical effects that somehow lead directly to aggression.

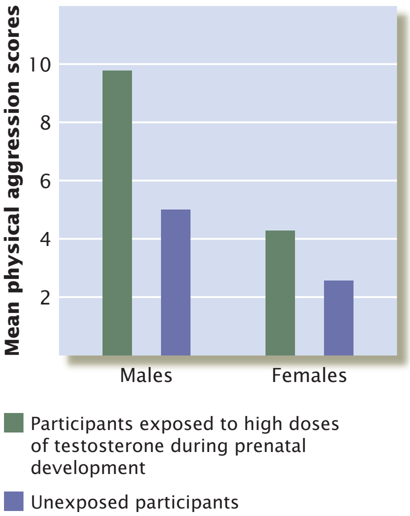

FIGURE 18.3

Testosterone and Aggression

In the study illustrated here, the children of women who had taken testosterone during pregnancy to prevent miscarriage became more aggressive than the mothers' other children of the same sex who had not been exposed to testosterone during prenatal development. This outcome held for both males and females.

Source: Reinisch, Ziemba-Davis, & Sanders (1991).

Learning and Cultural Mechanisms Although biological factors may increase or decrease the likelihood of aggression, cross-cultural research makes it clear that learning also plays a role. Aggressive behavior is much more common in individualist than in collectivist cultures, for example (Oatley, 1993). Cultural differences in the expression of aggression appear to stem in part from differing cultural values. For example, the Utku, an Inuit culture, view aggression in any form as a sign of social incompetence. In fact, the Utku word for *aggressive* also means "childish" (Oatley, 1993). The effects of culture on aggression can also be seen in the fact that the incidence of aggression in a given culture changes over time as cultural values change (Matsumoto, 2000).

Aggression can even differ from one part of a country to another. Consider the fact that more males in the southern United States commit homicide than males in the northern states (Cassel & Bernstein, 2007). As discussed later, this regional difference in the homicide rate may be related to the South's higher temperatures, but Richard Nisbett and other researchers (e.g., Cohen & Nisbett, 1997; Vandello, Cohen, & Ransom, 2008) have proposed that it is due to a *culture of honor* that is more commonly endorsed by southern males. One key aspect of this cultural

Following Adult Examples

Learning to express aggression is especially easy for children who live in countries plagued by war or sectarian violence because they see aggressive acts modeled for them all too often.

orientation is the need to defend one's honor, with violence if necessary, in response to a perceived insult. Studies testing this notion have indeed found that southern-born college students and professional athletes reacted much more angrily to a provocation than those born in the North and that southern high school students were much more likely than those in northern states to bring a weapon to school (Brown, Osterman, & Barnes, 2009; Cassel & Bernstein, 2007; Cohen et al., 1996; Timmerman, 2007).

The frequency of aggressive acts can be altered by rewards or punishment. People become more aggressive when rewarded for aggressiveness and less aggressive when punished for aggression (Geen, 1998). People also learn many aggressive responses by watching others (Bingenheimer, Brennan, & Earls, 2005; Bushman & Huesmann, 2010). Children, in particular, learn and perform many of the aggressive acts that they see modeled by others (Bandura, 1983). Albert Bandura's "Bobo" doll experiments, which are described in the chapter on learning, provide impressive demonstrations of the power of observational learning on aggression. The significance of observational learning is highlighted by studies of the effects of televised violence, also discussed in that chapter. For example, the amount of violent TV that children watch between 6 and 10 years of age predicts aggressiveness in these children even fifteen years later (Bushman & Huesmannn, 2010). Fortunately, not everyone who sees aggression becomes aggressive; individual differences in temperament, the modeling of nonaggressive behaviors by parents, and other factors can temper the effects of violent television. Nevertheless, observational learning, including the learning that comes through exposure to violent television, does play a significant role in the development and display of aggressive behavior (Anderson & Murphy, 2003; Bushman & Anderson, 2001; Konijin, Bijvank, & Bushman, 2007). Even listening to music whose lyrics describe or endorse violence can increase aggressive thoughts and hostile feelings (Anderson, Carnagey, & Eubanks, 2003).

In short, a person's accumulated experiences—including culturally transmitted teachings—combine with daily rewards and punishments to influence whether, when, and how aggressive acts occur (Baron & Richardson, 1994; Bettencourt et al., 2006).

THINKING CRITICALLY

Do Violent Video Games Make People More Aggressive?

A lot of research has been conducted on the impact of violent television on aggressiveness, but what about other forms of violent entertainment, such as video games? When these games first appeared in the late 1970s, they contained little or no violence, but by the 1990s, violent games such as *Mortal Kombat* and *Street Fighter* became extremely popular. The current flood of graphically violent games remain the favorites of young game-players. One survey of fourth-graders found that 59 percent of girls and 73 percent of boys preferred violent video games over nonviolent ones. In response to complaints from parents groups, the video game industry devised a rating system to try to keep the most violent games out of the hands of preteens and young teenagers, but many of the games that the system deems appropriate for these groups still contain considerable violent content (Funk et al., 1999). Further, according to another survey, 75 percent of young boys and 51 percent of young girls are playing video games that carry adults-only ratings (Anderson & Gentile, 2008). In other words, children in the United States have essentially unrestricted access to violent video games. If they can't buy a violent game in a store, they can download it from the Internet.

What am I being asked to believe or accept?

The groups that have objected to this situation are basing their concerns on the claim that playing violent video games can alter behavior in undesirable ways. Specifically, they say that exposure to violent video games increases the frequency of aggressive thoughts, feelings, and actions in people who play them (Anderson & Gentile, 2008).

What evidence is available to support the assertion?

The strongest evidence for this claim comes from an analysis by Craig Anderson and his colleagues of 135 correlational studies and laboratory experiments on violent video games (Anderson et al., 2010). The correlational studies have examined the relationship between the amount of time people spend playing these games and how aggressive they are. When the results of these studies were combined, a statistically significant positive relationship emerged. That is, the more time people spent playing violent video games, the more aggressive they tended to be. A significant correlation also appeared when the results of *longitudinal* studies were analyzed: Children who played more video games at one point in their lives were more aggressive at a later point.

Anderson also analyzed the results of laboratory experiments on violent video games. In these studies, researchers had randomly assigned participants to groups and then exposed them for varying lengths of time to games that contain varying amounts of violence and allow varying degrees of player involvement. After manipulating these independent variables, the researchers measured some aspect of aggression, which was the dependent variable in these experiments. Finally, they compared the amount of aggressiveness displayed by participants in the various groups. In one such experiment, participants played a violent video game in which the researchers manipulated two variables: whether the player could actively participate as one of the characters in the game or could only watch the actions of the game's characters and whether or not the characters bled when they were wounded (Farrar, Krcmar, & Nowak, 2006). They found that participants expressed more hostility and aggressive intentions during "first-person player" games that allowed them to be characters in the game and also when their victims bled when wounded. The combined results of many experiments like this one show that playing violent video games increases players' aggressive thoughts, feelings, and actions. There is also some evidence that playing violent video games may make people less likely to help others and less sensitive to other people's pain and suffering (Anderson et al., 2010).

Are there alternative ways of interpreting the evidence?

Like research on the effects of television violence, the results of correlational and experimental studies of violent video games have been questioned on several counts. The correlational studies have been challenged mainly because correlations do not allow us to draw conclusions about cause and effect. True, greater aggressiveness is associated with longer exposure to violent video games, but is this because the games are causing aggressiveness or because aggressive people are more inclined to play violent video games (Mitrofan, Paul, & Spencer, 2009)? The laboratory experiments have been criticized mainly because their methods may not reflect—and their results may therefore not apply to—what goes on in the world outside the laboratory (Goldstein, 2001). Do violent video games played in a lab have the same effects as they do when played at home, perhaps with friends? Do artificial laboratory measures of aggressiveness really tell us anything about how a person is likely to behave toward other people in daily life? Although experiments give researchers the control necessary to support cause-and-effect conclusions, critics argue that those conclusions may be of limited value in understanding the true impact of violent video games on aggressiveness (Ferguson, 2010).

Skeptics also point to experiments that have found *no* effect of violent video games on aggression (e.g., Ferguson & Rueda, 2010). They argue further that even if a statistically significant cause-and-effect relationship between violent video games and aggression does exist, it is not a very strong one (Ferguson & Kilburn, 2010; Sherry, 2001), especially when compared with other influences. They suggest, for example, that people's aggressiveness is affected far less by violent video games (and violent television) than by other factors, such as what children learn by seeing their families and friends behaving aggressively.

What additional evidence would help evaluate the alternatives?

Obviously, we need to know a lot more about the impact of violent video games. For example, how do they affect children of different ages? It would also be valuable to know what happens in the brains of people who play violent video games, and scientists are currently studying this question using a variety of neuroscience techniques. In one recent study, changes in event-related brain activity (see Figure 8.4 in the cognition and language chapter) indicated that playing violent video games made participants less sensitive to seeing violence and less upset by it (Bartholow, Bushman, & Sestir, 2006). Another study, using functional magnetic resonance imaging (fMRI), found that exposure to violent aspects of video games activates brain areas that are commonly associated with aggression (Weber, Ritterfeld, & Mathiak, 2006). Such studies cannot confirm that violent video games cause aggression, but their results support the possibility of a causal link and begin to provide some explanations about why that link might exist.

What conclusions are most reasonable?

Given the evidence available so far, it appears reasonable to say that violent video games probably have at least some effects on the people who play them. Questions about how strong the causal relationship is and how long it might last have not yet been answered. On the basis of the principles described in the chapter on learning, some researchers believe that violent video games may actually have a stronger impact on aggression than violent television both because game players can literally practice aggression as they engage in violent electronic acts and because they are rewarded for those violent acts by reaching the game's next level (e.g., Bushman & Anderson, 2007). Are these researchers correct? Are the effects of violent video games that strong, and are they likely to be long-lasting influences on aggressiveness? It will take much more research to definitively answer these questions, but it seems reasonable to suspect that the effects of prolonged exposure to violent video games will be quite similar to that of long exposure to violent television (Huesmann, 2010).

When Are People Aggressive?

LINKAGES What role does arousal play in aggression? (a link to Motivation and Emotion, p. 418)

In general, people are more likely to be aggressive when they are both physiologically aroused and experiencing angry or hostile thoughts and feelings (Anderson & Bushman, 2002a). They tend either to lash out at those who make them angry or to displace their anger onto defenseless targets such as children or pets. However, aggression can also be made more likely by other forms of emotional arousal. One emotion that has long been considered a major cause of aggression is *frustration,* which occurs when we are prevented from reaching some goal.

Frustration and Aggression Suppose that a friend interrupts your studying for an exam by dropping by to borrow a book. If things have been going well and you are feeling confident about the exam, you are likely to be friendly and helpful. But what if you are feeling frustrated because your friend's visit is the fifth interruption in the past hour? Under these emotional circumstances, you may react aggressively, perhaps snapping at your startled visitor for bothering you.

Your aggressiveness in this situation conforms to the predictions of the **frustration-aggression hypothesis**, originally developed by John Dollard and his colleagues (1939). They proposed that frustration always results in aggression and that aggression will not occur unless a person is frustrated. Research on this hypothesis, however, has shown that it is too simple and too general. For one thing, frustration sometimes produces depression and withdrawal, not aggression (Berkowitz, 1998). In addition, not all aggression is preceded by frustration (Berkowitz, 1994).

frustration-aggression hypothesis A proposition that frustration always leads to some form of aggressive behavior.

After many years of research, Leonard Berkowitz (1998) suggested some substantial modifications to the frustration-aggression hypothesis. In his *aversively stimulated* *aggression theory,* he proposed that it may be stress in general rather than frustration in particular that can produce a readiness to act aggressively. Once this readiness exists, cues in the environment that are associated with aggression will often lead a person to behave aggressively. The cues might be guns or knives, people arguing on TV, violent song lyrics or game images, or other triggers. Neither stress alone nor the cues alone are sufficient to set off aggression. When combined, however, they often do set it off. Support for this aspect of Berkowitz's theory has been quite strong (Bushman & Huesmann, 2010).

Berkowitz also argues that the direct cause of most kinds of aggression is negative feelings, or *negative affect,* caused by something unpleasant. He says that the greater the negative affect, whether it is caused by frustrating circumstances or other sources, the stronger the readiness to behave aggressively (Berkowitz, 1998). Negative affect can be aroused by pain, for example. Research suggests that people in pain do tend to become aggressive, regardless of the cause of their pain. In one study, participants whose hands were placed in painfully cold water became more aggressive toward other people than participants whose hands were in water of room temperature (Berkowitz, 1998).

Generalized Arousal Imagine that you have just jogged for 3 miles. You are hot, sweaty, and out of breath, but you are not angry. Still, the physiological arousal caused by jogging may increase the probability that you will become aggressive if, say, a passerby shouts an insult (Zillmann, 1988). Why? The answer lies in a phenomenon described in the chapter on motivation and emotion: Arousal from one experience may carry over to an independent situation, producing what is called *excitation transfer.* So the physiological arousal caused by jogging may intensify your reaction to an insult (Harrison, 2003).

By itself, however, generalized arousal does not lead to aggression. It is most likely to produce aggression when the situation contains some reason, opportunity, or target for aggression (Zillmann, 2003). In one study, for example, people engaged in two minutes of vigorous exercise. Then they had the opportunity to deliver an electrical shock to another person. The participants chose high levels of shock only if they were first insulted (Zillmann, Katcher, & Milavsky, 1972). Apparently, the arousal resulting from the exercise made aggression more likely; the insult "released" it.

Other research suggests that men who are aroused by watching violent pornography may be more likely to commit rape or other forms of aggression against women. In one experiment, for example, male participants were told that a person in another room (actually the experimenter's assistant) would be performing a learning task and that they were to administer an electric shock every time the person made a mistake. The intensity of shock could be varied (as in the Milgram studies, no shock actually reached the assistant), but participants were told that changing the intensity would not affect the speed of learning. So the shock intensity (and presumed pain) that they chose to administer was considered to be a measure of aggression. Before the learning trials began, some participants watched a film in which several men had sex with the same woman, against her will. These participants' aggressiveness toward women during the learning experiment was greater than that of men who did not watch the film (Donnerstein, 1984). There was no parallel increase in aggression against other men, indicating that the violent pornography didn't create a generalized increase in aggression but did create an increase in aggressiveness directed toward women.

Such effects do not appear in all men, however (Ferguson & Hartley, 2009; Seto, Maric, & Barbaree, 2001). One study of about 2,700 men in the United States found that men who are not hostile toward women and who rarely have casual sex showed little, if any, change in sexual aggressiveness after viewing aggressive pornography. In contrast, among men who are high in promiscuity and hostility, watching aggressive pornography was followed by a dramatic increase in the chances that these men would engage in sexual aggression (Malamuth, Addison, & Koss, 2000). In fact, 72 percent of the men who frequently used pornography and were high in promiscuity and hostility had actually engaged in sexually aggressive acts (see Figure 18.4). Viewing pornography appears to have similar effects on convicted sex offenders who have been placed

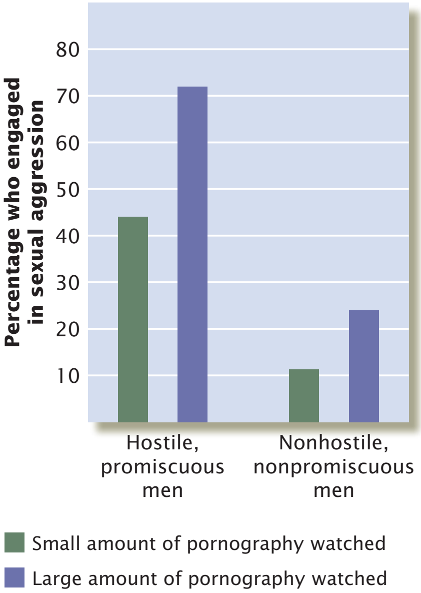

FIGURE 18.4

Pornography and Sexual Aggression

Extensive exposure to pornography does not by itself make most men more likely to engage in sexual aggression. However, among men who are hostile toward women and have a history of sexual promiscuity, those who view a lot of pornography are much more likely to engage in sexual aggression.

Source: Adapted from Malamuth (1998).

on probation or released on parole, and the effects are especially pronounced among those who had committed the most serious sex crimes (Kingston et al., 2008).

These findings support the notion that aggression is not caused solely by a person's characteristics or by the particular situation a person is in. Instead, the occurrence and intensity of aggression are determined by the joint influence of individual characteristics and environmental circumstances (Klinesmith, Kasser, & McAndrew, 2006).

Environmental Influences on Aggression The links between stress, arousal, and aggressive behavior point to the possibility that stressful environmental conditions can make aggressive behavior more likely (Anderson, 2001). This possibility is one of the research topics in **environmental psychology**, the study of the relationship between people's physical environment and their behavior (Bell et al., 2000). One aspect of the environment that clearly affects social behavior is the weather, especially temperature. High temperature is a source of stress and arousal, so it might be expected to correlate with aggressiveness. The results of many studies conducted in several countries show that many kinds of aggressive behaviors are indeed more likely to occur during hot summer months than at any other time of the year (Anderson et al., 2000; Bushman, Wang, & Anderson, 2005; see Figure 18.5).

Noise also tends to make people more likely to display aggression, especially if the noise is unpredictable and irregular (Geen & McCown, 1984). Living arrangements, too, can influence aggressiveness. Compared with the tenants of crowded apartment buildings, those in buildings with relatively few residents are less likely to behave aggressively (Bell et al., 2000). This difference appears to be due in part to how people feel when they are crowded. Crowding tends to create physiological arousal and to make people tense, uncomfortable, and more likely to report negative feelings (Oskamp & Schultz, 1998). This arousal and tension can influence people to like one another less and to be more aggressive. One study of juvenile delinquents found that the number of behavior problems they displayed (including aggressiveness) was directly related to how crowded their living conditions had become (Ray et al., 1982).

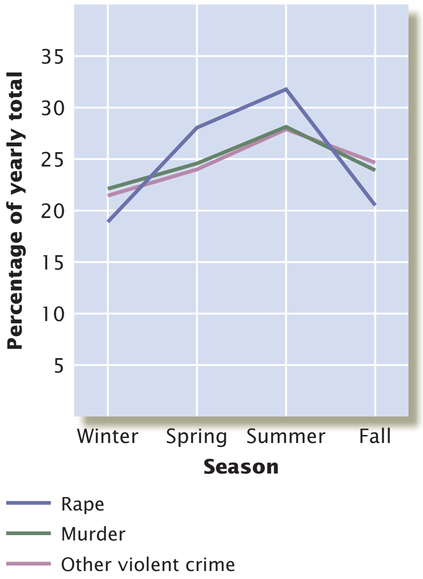

FIGURE 18.5

Effects of Temperature on Aggression

Studies from around the world indicate that aggressive behaviors are most likely to occur during hot summer months. These studies support the idea that environmental factors can affect aggression.

Source: From Anderson, C.A. & Anderson, K.P. "Temperature and Aggression: Paradox, Controversy, and a (Fairly) Clear Picture," in R.G. Greene & E. Donnerstein, eds., *Human Aggression*, p. 279, figure 10.9. Copyright © 1998. Reprinted with permission of Elsevier.

Crowding and Aggression

APPLYING PSYCHOLOGY Studies of prisons suggest that as crowding increases, so does aggression (Lahm, 2008; Lawrence & Andrews, 2004). Environmental psychologists are working with architects on the design of prisons that minimize the sense of crowding and that may help prevent some of the violence that endangers staff and prisoners.

environmental psychology The study of the relationship between behavior and the physical environment.

Altruism and Helping Behavior

Like all acts of terrorism, the 2001 attacks on the World Trade Center and the Pentagon were examples of human behavior at its worst. But like all tragedies, they drew responses that provide inspiring examples of human behavior at its best. Michael Benfante and John Cerqueira were working in the World Trade Center when one of the hijacked planes struck their building. They headed for a stairwell, but they didn't just save themselves. Although it slowed their own escape, they chose to carry Tina Hansen, a wheelchair-bound coworker, down sixty-eight flights of stairs to safety. David Theall was in his Pentagon office when another hijacked plane hit the building not far from his desk. He could have escaped the rubble immediately, but he first located a dazed officemate and led him, along with seven other coworkers, to safety. And no one will ever forget the heroism of the hundreds of New York City firefighters, police officers, and emergency workers who risked and even lost their lives trying to save others. Acts of selflessness and sacrifice were common that day and in the days, weeks, and months that followed. Police officers, medical personnel, search-and-rescue specialists, and just ordinary people came to New York from all over the United States to help clear wreckage, look for survivors, and recover bodies. More than $1 billion in donations to the Red Cross and other charitable organizations poured in to help victims; one celebrity telethon raised $150 million in two hours. There was also a dramatic increase in many other forms of prosocial behavior, including volunteering to work for all kinds of charities (Penner, Brannick, et al., 2005).

All of these actions are examples of **helping behavior** (also known as **prosocial behavior**), which is defined as any act that is intended to benefit another person. Helping can range from picking up dropped packages to donating a kidney. Closely related to helping is **altruism**, an unselfish concern for another person's welfare (Penner, Dovidio, et al., 2005). Let's consider some of the reasons behind helping and altruism, along with some of the conditions under which people are most likely to help others.

One of Many Heroes

Along with his colleague Michael Benfante, John Cerqueira (shown here) risked his life on September 11, 2001, to help a handicapped coworker escape from the sixty-eighth floor of the World Trade Center. Hundreds of other heroic acts of helping took place that day, and less dramatic examples occur every day throughout the world.

helping behavior (prosocial behavior) Any act that is intended to benefit another person.

altruism An unselfish concern for another person's welfare.

A Young Helper

Even before their second birthday, some children offer help to people who are hurt or crying by snuggling, patting, or offering food or even their own teddy bears.

Why Do People Help?

The tendency to help others begins early, although at first it is not spontaneous. In most cultures, very young children generally help others only when they are asked to do so or are offered a reward (Grusec, Davidov, & Lundell, 2002). Still, researchers have found that children as young as 18 months attempt to help others (Dunfield & Kuhlmeier, 2010; Knafo et al., 2008; Over & Carpenter, 2009). As they grow, so does the role of social influence. Children use helping behavior to gain social approval, and their efforts at helping become more elaborate. Their helping behaviors are shaped by the social norms established through the examples set by their families and the broader culture (Grusec & Goodnow, 1994). In addition, children are praised and given other rewards for helpfulness but are scolded for selfishness. Eventually, children come to believe that helping is good and that they are good when they help. By the late teens, people often help others even when no one is watching and no one will know that they did so (Grusec, Davidov, & Lundell, 2002). There are three major theories about why people help even when they cannot expect any external rewards for doing so.

Arousal: Cost-Reward Theory One approach to explaining why people help is called the **arousal: cost-reward theory** (Piliavin et al., 1981). This theory proposes that the sight of a person who is suffering causes distress and anxiety and that these feelings motivate the observer to do something to reduce the unpleasant arousal. Several studies have shown that all else being equal, the more physiologically aroused bystanders are, the more likely they are to help someone in an emergency (Dovidio et al., 2006). Before rushing to a victim's aid, however, the bystander will first evaluate two aspects of the situation: the costs associated with helping and the costs (to the bystander and the other person) of not helping. Whether or not the bystander actually helps depends on the outcome of this evaluation (Dovidio et al., 1991). If the costs of helping are low (as when helping someone pick up a dropped grocery bag) and the costs of not helping are high (as when the other person is physically unable to do this alone), the bystander will almost certainly help. However, if the costs of helping are high (as when the task is to load a heavy box into a car) and the costs of not helping are low (as when the person is strong enough to manage the task alone), the bystander is unlikely to offer help. This theory is attractive partly because it is comprehensive enough to provide a framework for explaining research findings on the factors that affect helping.

One of these factors is the *clarity of the need for help,* which has a major impact on whether people provide help (Dovidio et al., 2006). In one study, undergraduate students were waiting alone in a campus building when a staged accident took place outside. A window washer screamed as he and his ladder fell to the ground. He then began to clutch his ankle and groan in pain. All of the students looked out a window to see what had happened, but only 29 percent of them did anything to help. Other students experienced the same situation with one important difference: The man *said* he was hurt and needed help. In this case, more than 80 percent of the students came to his aid (Yakimovich & Saltz, 1971). Why so many? Apparently, this one additional cue eliminated any uncertainty about whether the person needed help. This cue also raised the perceived costs to the victim of not offering help. As these costs become higher, helping becomes more likely. If this laboratory study seems unrealistic, consider the March 2000 case of a 62-year-old woman in Darby, Pennsylvania. She was walking to the grocery store when she was pushed from behind by an attacker. She fended him off and then did her shopping as usual. It was only when she got home and her daughter saw the handle of a knife protruding from her back that she realized that the assailant had stabbed her! No one in the grocery store said anything to her about the knife, let alone offered to help. Why? The most likely explanation is that the woman didn't say or do anything to suggest that help was needed.

The *presence of others* also has a strong influence on the tendency to help. Somewhat surprisingly, though, their presence tends to make helping behavior *less* likely (Garcia et al., 2002). For example, in November 2000 in London, a 10-year-old boy who had

arousal: cost-reward theory A theory attributing people's helping behavior to their efforts to reduce the unpleasant arousal they feel in the face of someone's need or suffering.

been stabbed by members of a street gang lay ignored by passersby as he died. In June 2007, customers in a Wichita, Kansas, convenience store did nothing to help a 27-year-old woman who eventually bled to death after being stabbed during an argument. In fact, surveillance video shows five shoppers stepping over her, including one who stopped only long enough to take a picture with a cell phone ("Kansas Store Video," 2007). And in October 2009, a dozen people in Richmond, California, simply watched as a 15-year-old girl was beaten and gang-raped outside her high school homecoming dance ("Dozen People Watched," 2009). Whenever such cases come to light, journalists and social commentators express dismay about the cold, uncaring attitudes that seem to exist among people who live in big cities. But psychologists believe that something about the situation surrounding such events deters people from helping.

The numerous studies of helping behavior have revealed a phenomenon, known as the **bystander effect**, that may explain the inaction of potential helpers in London, Kansas, and California: The likelihood that someone will help in an emergency tends to decrease as the number of people present increases (Garcia et al., 2002). One explanation for why the presence of others often reduces helping is that each person thinks someone else will help the victim. That is, seeing other bystanders allows each individual to experience a *diffusion of responsibility* for taking action, which lowers the costs of not helping (Dovidio et al., 2006).

The degree to which the presence of other people inhibits helping may depend on who those other people are. When they are strangers, poor communication may inhibit helping. People often have difficulty speaking to strangers, particularly in an emergency, and without speaking, they have difficulty knowing what the others intend to do. According to this logic, if people are with friends rather than strangers, they should be less uncomfortable, more willing to discuss the problem, and thus more likely to help.

In one experiment designed to test this idea, an experimenter left a research participant in a waiting room under one of four conditions: alone, with a friend, with a stranger, or with a stranger who was an assistant to the experimenter (Latané & Rodin, 1969). The experimenter then stepped behind a curtain into an office. For a few minutes, she could be heard opening and closing the drawers of her desk, shuffling papers, and so on. Then there was a loud crash, and she screamed, "Oh, my God … My foot, I … I can't move it. Oh, my ankle … I can't get this … thing off me." Then the participant heard her groan and cry.

Diffusion of Responsibility

Does the man on the sidewalk need help? The people nearby are probably not sure, and they might assume that if he does, someone else will help him. Research on factors affecting helping (e.g., Flynn & Lake, 2008) suggests that if you ever need help, especially in a crowd, it is important not only to ask for help but also to tell a specific onlooker to take specific action (for example, "You, in the yellow shirt, please call an ambulance!").

bystander effect A phenomenon in which the chances that someone will help in an emergency decrease as the number of people present increases.

Would the participant go behind the curtain to help? Once again, people were most likely to help if they were alone. When one other person was present, participants were more likely to communicate with each other and to offer help if they were friends than if they were strangers. When the stranger was the experimenter's assistant (who had been instructed not to help), very few participants offered to help. Other studies have confirmed that bystanders' tendency to help increases when they know one another (Rutkowski, Gruder, & Romer, 1983).

Research suggests that the *personality of the helper* also plays a role in helping. Some people are simply more likely to help than others. Consider the Christians who risked their lives to save Jews from the Nazi Holocaust. Researchers interviewed hundreds of these rescuers many years later and compared their personalities with those of people who had a chance to save Jews but did not do so (Fagin-Jones & Midlarsky, 2007; Oliner & Oliner, 1988). The rescuers were found to have more empathy (the ability to understand or experience another's emotional state), more concern about others, a greater sense of responsibility for their own actions, and a greater sense of self-efficacy (confidence that their efforts will succeed). Louis Penner and his associates (Penner, 2002; Penner & Finkelstein, 1998) have found that these kinds of personality traits predict a broad range of helping behaviors, from the speed with which bystanders intervene in an emergency to the amount of time volunteers spend helping AIDS patients. Consistent with the arousal: cost-reward theory, these personality characteristics are also correlated with people's estimates of the costs of helping and not helping. For example, empathic individuals usually estimate the costs of not helping as high, and people with a sense of self-efficacy usually rate the costs of helping as low (Penner et al., 1995). These patterns of cost estimation may partially explain why such people tend to be especially helpful.

Valuable as it is, the arousal: cost-reward theory cannot account for all aspects of helping. For instance, it cannot easily explain why *environmental factors* affect helping. Research conducted in several countries has revealed, for example, that people in urban areas are generally less helpful than those in rural areas (Dovidio et al., 2006). Why? The explanation probably has more to do with the stressors found in cities than with city living itself. One study of twenty-four U.S. cities found that the greater a city's size and density (number of people per square mile), the less likely people were to help others. Helping was also much less likely in cities where stressful economic conditions were greatest (Levine, Reysen, & Ganz, 2008). Similar results have been found in cities in the United Kingdom, the Middle East, and Africa (Hedge & Yousif, 1992; Yousif & Korte, 1995). Why should stress make people less helpful? Two explanations have been suggested. The first is that stressful environments create bad moods—and generally speaking, people in bad moods are less likely to help (Salovey, Mayer, & Rosenhan, 1991). A study of department store clerks, for example, found that those in a good mood were much more likely to help customers than those who were feeling grouchy (Forgas, Dunn, & Granland, 2008). A second possibility is that noise, crowding, and other urban stressors create too much stimulation. To reduce this excessive stimulation, people may pay less attention to their surroundings, which might include individuals who need help.

It is also difficult for the arousal: cost-reward theory to predict what bystanders will do when the cost of helping and the cost of not helping are *both* high. In these cases, helping (or not helping) may depend on several situational factors and sometimes on the personality of the potential helper. There may also be circumstances in which cost considerations may not be the major cause of a decision to help or not help. A second approach to helping considers some of these circumstances.

empathy-altruism theory (empathy-altruism helping theory) A theory suggesting that people help others because of empathy with their needs.

Empathy-Altruism Theory The second approach to explaining helping is embodied in **empathy-altruism theory** (also known as **empathy-altruism helping theory**), which maintains that people are more likely to engage in *altruistic,* or unselfish, helping—even when the cost of helping is high—if they feel empathy toward the person in need (Batson, 2010). In one experiment illustrating this phenomenon,

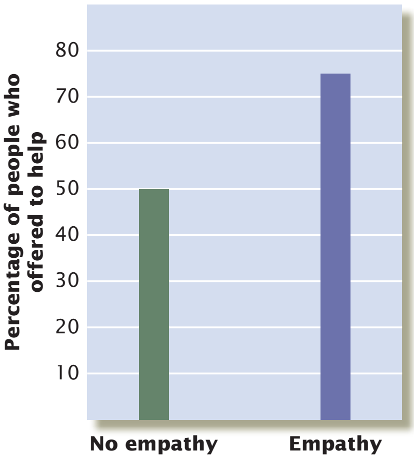

FIGURE 18.6

The Effect of Empathy on Helping

After hearing a staged interview with a woman who supposedly needed to raise money for her family, participants in this experiment were asked to help her. Those who were led to empathize with the woman were much more likely to offer their help than those who did not empathize. These results are consistent with empathy-altruism theory.

Source: Adapted from Batson et al. (1997).

participants listened to a tape-recorded interview with a female student. The student told the interviewer that her parents had been killed in an automobile accident, that they had had no life insurance, and that she was now faced with the task of finishing college while taking care of a younger brother and sister. She said that these financial burdens might force her to quit school or give up her siblings for adoption. None of this was true, but the participants were told that it was. Further, before listening to the woman's story, half the participants were given additional information about her that was designed to promote strong empathy. Later, all the participants were asked to help the woman raise money for herself and her siblings (Batson et al., 1997). The critical question was whether the participants who heard the additional empathy-promoting information would help more than those who did not have that information. Consistent with the empathy-altruism theory, more participants in the empathy condition than in the nonempathy condition offered to help (see Figure 18.6).

Were the people who offered help in this experiment being utterly altruistic, or could there be a different reason for their actions? This is a hotly debated question. Some researchers dispute the claim that this study illustrated true altruistic helping. They suggest that people help in such situations for more selfish reasons, such as relieving the distress they experienced after hearing of the woman's problems (Maner et al., 2002). The final verdict on this question is not yet in.

Evolutionary Theory The evolutionary approach to social psychology offers a third way of explaining helping. This approach views many human social behaviors as echoes of actions that contributed to the survival of our prehistoric ancestors (Buss, 2009). At first glance, it may not seem reasonable to apply evolutionary theory to helping and altruism because helping others at the risk of one's own well-being doesn't seem to be adaptive. If we die while trying to save others, it is their genes, not ours, that will survive. In fact, according to Charles Darwin's concept of the survival of the fittest, helpers—and their genes—should have disappeared long ago. Contemporary evolutionary theorists suggest, however, that Darwin's thinking about natural selection focused too much on the survival of the fittest *individuals* and not enough on the survival of their genes in others. Accordingly, the concept of survival of the fittest has been replaced by the concept of *inclusive fitness,* the survival of one's genes in future generations (Hamilton, 1964; Kruger, 2003; West & Gardner, 2010). Because

Family Ties

Research indicates that people are more likely to donate organs to family members than to strangers. This pattern may reflect greater attachment or a stronger sense of social obligation to relatives than to others. Psychologists who take an evolutionary approach suggest that such helpful attitudes and actions have evolved because they are adaptive. When, as in the case of these sisters, one family member donates a kidney to save the life of another, the genes they share are more likely to survive.

© Mark C. Burnett/Photo Researchers, Inc.

we share genes with our relatives, helping or even dying for a cousin, a sibling, or above all, our own child potentially increases the likelihood that at least some of our genetic characteristics will be passed on to the next generation through the beneficiary's future reproduction (Rachlin & Jones, 2008). So *kin selection*—helping a relative survive—may produce genetic benefits even if it provides no personal benefits for the helper (Brown & Brown, 2006).

There is considerable evidence that kin selection occurs among birds, squirrels, and other animals. The more closely the animals are related, the more likely they are to risk their lives for one another. Studies in a wide variety of cultures show the same pattern of helping among humans (Buss, 2009). People in the United States are three times as likely to donate a kidney to a relative than to a nonrelative (Borgida, Conner, & Monteufel, 1992), and identical twins (who have exactly the same genes) are much more willing to help one another than fraternal twins or siblings, who share only 50 percent of their genes (Segal, 1999).

FOCUS ON **RESEARCH METHODS**

Does Family Matter?

In and of themselves, data on kin selection do not confirm evolutionary explanations of helping and altruism. The greater tendency to donate organs to relatives could also be due to the effects of empathy toward more familiar people, pressure from family members, or other social influence processes. To control for the effects of these confounding variables, some researchers have turned to the laboratory to study the role of evolutionary forces in helping behavior.

What was the researchers' question?

Eugene Burnstein, Christian Crandell, and Shinobu Kitayama (1994) wanted to know whether people faced with a choice of whose life to save would behave in line with the concept of kin selection. These investigators reasoned that if kin selection does affect helping, the more genetically related two people are—the more genes they share in common—the more inclined they should be to save each other's life. Further, if this kind of prosocial behavior evolved because it preserves one's own genes in others, the tendency to save a close relative should be lessened if that relative is unlikely to produce offspring and therefore less likely to help preserve the helper's genes.

How did the researchers answer this question?

The most direct way to test these predictions would be to put people's lives in danger and then observe which (if any) of their relatives try to save them. Such an experiment would be unthinkable, of course, so Burnstein and his colleagues used a simulation, or *analogue,* methodology. Specifically, they asked people to imagine a series of situations and then to say how they would respond if the situation were real.

The participants in the analogue experiment were 110 men and 48 women enrolled at universities in Japan and the United States. The first independent variable was the kind of help that was needed. On the basis of random assignment, some participants were asked to imagine life-or-death situations in which there was time to save only one of three people who were asleep in separate rooms of a burning house. The remaining participants were asked to imagine everyday situations in which they had time to help only one of three people who each needed a small favor. The other independent variables were the characteristics of the people needing help in each situation—their age, sex, physical health, and genetic relatedness to the potential helper. The dependent variable was the participants' choice of which person they would help.

What did the researchers find?

In accordance with evolutionary theory, the participants were more than twice as likely to say they would save the life of a close relative than that of an unrelated friend. Also, the more closely related the endangered people were to the potential helpers, the

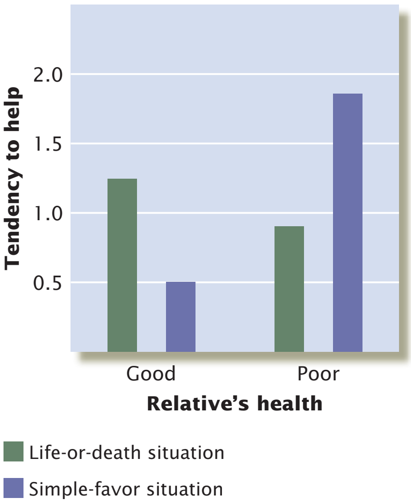

FIGURE 18.7

Kin Selection and Helping

TRY THIS In this analogue experiment, students said they would be more likely to save the life of a healthy relative than a sick one but more likely to do a favor for the sick relative. Results like these have been cited in support of evolutionary theories of helping behavior. Ask a few friends to say which member of their families they would save first in the event of a fire. To what extent were their responses consistent with the results of the kin selection analogue research described in this section?

Source: Burnstein, Crandell, & Kitayama (1994).

more likely they were to be saved. Did these results occur simply because people tend to help closer relatives in any situation? Probably not. When the participants imagined situations in which only small favors were involved, they were only slightly more likely to help a close relative than a distant one.

Another major prediction of evolutionary theory was supported as well. Several findings indicated that even close relatives might not be saved if they were unlikely to produce offspring. For example, the participants were more willing to do a small favor for a 75-year-old relative than for a 10- or 18-year-old relative, but they were much more likely to save the lives of the younger relatives. Similarly, they were more likely to do a favor for a sick relative than for a healthy one; but in a life-or-death situation, they chose to save the healthy relative more often than the sick one (see Figure 18.7). Finally, the participants were more likely to save the life of a female relative than that of a male relative, unless the female was past childbearing age. There were no substantial differences between the responses of students in the United States and those in Japan.

What do the results mean?

The results of this experiment generally support the concept of kin selection, which says that the tendency to help close relatives evolved because, genetically speaking, it helps the helper. Specifically, if we save the life of a relative and that relative is able to produce offspring, more of our genes will be represented in the next generation. Evolutionary psychologists see these results as providing confirmation that kin selection affects the decisions people make about saving the life of another person and hence that there is an evolutionary basis for helping.

What do we still need to know?

The findings reported by Burnstein and his colleagues are consistent with the predictions of evolutionary theory, but they must be interpreted with caution and in light of the methods that were used to obtain them. Analogue studies give clues to behavior—and allow experimental control—in situations that approximate, but may not precisely duplicate, situations outside the laboratory. These studies tend to be conducted when it would be unethical or impractical to expose people to "the real thing." The more closely the analogue approximates the natural situation, the more confident we can be that conclusions drawn about behavior observed in the laboratory will apply, or generalize, to the world beyond the laboratory.

In an analogue experiment such as this one, we might question how closely the natural situation was approximated. For one thing, the participants predicted what their responses would be in hypothetical situations. Those responses might be different if the students were actually in the situations described. So although the analogue methodology in this study allowed the researchers to show that kin selection *could* play a role in human helping behavior, they did not demonstrate that it *does* play a role.

The study also failed to identify the mechanisms whereby biological tendencies are translated into thoughts that lead to helpful actions (Kruger, 2003). It is highly unlikely that the participants were thinking, "I'll help a close relative because it will preserve my genes." So what conscious thoughts or feelings led to their choices? Another analogue study by Josephine Korchmaros and David Kenny (2001) may provide a partial answer to this question. The people who needed help in this simulation were described using the names of the participants' actual family members. The researchers also measured the strength of the emotional ties between the participants and these particular people. The results suggested that genetic closeness was related to emotional closeness. Perhaps, then, emotional closeness provides the mechanism that drives the choice of whom to help. It may be that we are biologically predisposed to feel emotionally closer to closer relatives and thus more likely to help them if their lives are in danger. These feelings in turn serve to increase the chances that some of our genes will survive in those close relatives.

IN REVIEW Theories of Helping Behaviors

Theory	Basic Premise	Important Variables
Arousal: cost-reward	People help in order to reduce the unpleasant arousal caused by another person's distress. They attempt to minimize the costs of doing this.	Factors that affect the costs of helping and of not helping
Empathy-altruism	People sometimes help for utterly altruistic reasons. They are motivated by a desire to increase another person's well-being.	The amount of empathy that one person feels for another
Evolutionary	People help relatives because it increases the chances that the helper's genes will survive in future generations.	The biological relationship between the helper and the recipient of help

1. If you could save only one person from a burning house, the ____________ theory of helping would predict that it would be your own child rather than, say, a grandparent.

2. In an emergency, are you more likely to receive help in a nearly empty bus or in a crowded bus terminal?

3. People who have empathy for others are ____________ likely to be helpful.

This is a reasonable possibility, and it has been supported by other research evidence (Rachlin & Jones, 2008), but remember that even though evolutionary theory may explain some general human tendencies to help, it cannot predict the behavior of specific individuals in specific situations (Penner, Dovidio, et al., 2005). Like all other behavior, helping and altruism depend on the interplay of many genetic and environmental factors—including interactions between particular people and particular situations. (See "In Review: Theories of Helping Behaviors" for a summary of the major reasons why people help and the conditions under which they are most likely to do so.)

Cooperation, Competition, and Conflict

Helping is one of several ways in which people *cooperate* with one another. **Cooperation** is any type of behavior in which people work together to attain a common goal (Dovidio et al., 2006). For example, several law students might form a study group to help one another pass a difficult exam. But people can also engage in **competition**, trying to attain a goal for themselves while denying that goal to others. So those same students might later compete with one another for a single job opening at a prestigious law firm. Finally, **conflict** results when one person or group believes that another stands in the way of their achieving a goal. When the students become attorneys and represent opposing parties in a legal dispute, they will be in conflict. One way in which psychologists have learned about all three of these behaviors is by studying social dilemmas (Weber, Kopelman, & Messick, 2004).

cooperation Any type of behavior in which people work together to attain a goal.

competition Behavior in which individuals try to attain a goal for themselves while denying that goal to others.

conflict The result of a person's or group's belief that another person or group stands in the way of their achieving a valued goal.

social dilemma A situation in which actions that produce rewards for one individual will produce negative consequences if adopted by everyone.

prisoner's dilemma game A social dilemma scenario in which mutual cooperation guarantees the best mutual outcome.

Social Dilemmas

Social dilemmas are situations in which an action that brings rewards for the individual will, if widely adopted, produce negative consequences for the group (Aronson, Wilson, & Akert, 2010). For instance, during a drought, individual homeowners are better off in the short run if they water their lawns as often as necessary to keep the grass from dying, but if everyone ignores local water restrictions, there will be no drinking water for anyone in the long run. Social psychologists have studied situations like this by conducting experiments using the two-person "prisoner's dilemma" game.

The Prisoner's Dilemma Game The **prisoner's dilemma game** is based on a scenario in which two people are separated for questioning immediately after being arrested on suspicion of having committed a serious crime (Komorita & Parks, 1996). The prosecutor believes they are guilty but doesn't have enough evidence to convict them. Each prisoner

Cooperation, Competition, Conflict, and Cash

Cooperation, competition, and conflict can all be seen on *Survivor,* a television series in which people try to win money by staying the longest in some remote location. Early on, contestants cooperate with members of their own teams, but as more and more people are eliminated, even team members compete with one another. When only two people remain, each stands in the way of the other's goal of winning, so they are in direct conflict.

© CBS-TV/The Kobal Collection/Robert Voets

can either confess or not, but they are told that if they both refuse to confess, each will be convicted of a minor offense and will be jailed for one year. If they both confess, the prosecutor will recommend a five-year sentence for each. However, if one prisoner remains silent and the other confesses to what they did, the prosecutor will allow the confessing prisoner to go free, whereas the other will serve the maximum ten-year sentence.

Each prisoner faces a dilemma. Part A of Figure 18.8 outlines the possible outcomes. Obviously, the strategy that will guarantee the best *mutual* outcome—short sentences for both prisoners—is cooperation. In other words, neither should confess. But the prisoner who remains silent runs the risk of receiving a long sentence if the other prisoner confesses. Further, the prisoner who confesses will benefit if the other prisoner doesn't talk. In other words, each prisoner has an incentive to compete for freedom by confessing. But if they *both* compete and confess, each will end up going to jail for longer than if they had kept quiet.

In the typical prisoner's dilemma experiment, two people sit at separate control panels. Each of them has a red button and a black button, one of which is to be pushed on each of many trials. Pressing the black button is a cooperative response. Pressing the red button is a competitive response. For example, on a given trial, if both participants press their black buttons, each wins $5. If both press their red buttons, they earn only $1. However, if one player presses the red button and the other presses the black button, the one who pressed the red button will win $10, and the other will win nothing.

Part B of Figure 18.8 shows the possible outcomes for each trial. Over the course of the experiment, the combined winnings of the players are greatest if each presses the black button—that is, if they cooperate. By pressing the black button, however, a

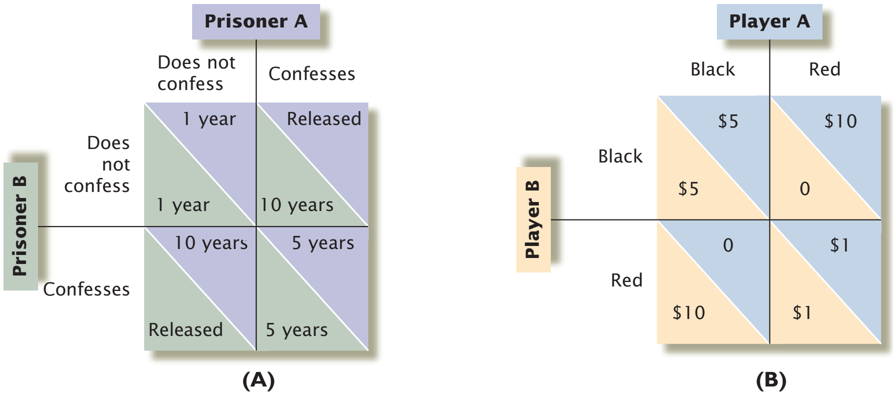

FIGURE 18.8

The Prisoner's Dilemma Game

In the prisoner's dilemma game, mutual cooperation benefits each person and mutual competition is harmful to both. However, one party can take advantage of the other's cooperativeness. These diagrams show the potential payoffs for prisoners—and research participants—in prisoner's dilemma game situations.

player becomes open to exploitation, because on any trial, the other might press the red button and take all the winnings. So each player stands to benefit the most individually by pressing the red button occasionally. The prisoner's dilemma game is what psychologists call a *mixed-motive conflict*—there are good reasons to cooperate and also good reasons to compete.

What happens when people play this game? Overall, there is a strong tendency to respond competitively. People find it difficult to resist the competitive choice on any given trial (Lodewijkx, Rabbie, & Visser, 2006). This choice wins them more money on that trial, but in the long run, they gain less than they would have gained through cooperation.

If acting competitively leads to smaller rewards in the long run, why do people persist in competing? There seem to be two reasons (Komorita, 1984). First, winning more than an opponent seems to be rewarding in itself. In the prisoner's dilemma game, many people want to outscore an opponent even if the result is that they win less money overall. Second, and more important, once several competitive responses are made, the competition seems to feed on itself (Insko et al., 1990). Each person becomes distrustful of the other, and cooperation becomes increasingly difficult. The more competitive one person acts, the more competitive the other becomes (McClintock & Liebrand, 1988).

Resource Dilemmas Psychologists interested in cooperation, competition, and conflict have also concentrated on social dilemmas in which people share a common resource. In this situation, called a *resource dilemma* (De Cremer & van Dijk, 2008), there are built-in conflicts between the interests of the individual and those of the group and also between people's short-term and long-term interests (De Dreu, 2010). There are two kinds of resource dilemmas. In the *commons dilemma,* people have to decide how much to take from a common resource. In the *public goods dilemma,* people must decide how much to contribute to a common resource. An example of the commons dilemma would be a situation in which farmers all want to draw water for their crops from the same lake. Each individual farmer would benefit greatly from unrestricted use of the water, but if all the farmers did the same, the water would soon be gone. Tax laws provide an example of the public goods dilemma. You would benefit greatly in the short run if you didn't pay any taxes, but if everyone failed to pay, no one would have police and fire protection, highway repairs, national defense, or other vital government services. How can people facing such dilemmas be prompted to cooperate?

Promoting Cooperation

Communication can reduce people's tendency to act competitively (Pavitt et al., 2007). Unfortunately, however, not all communication increases cooperation, just as not all contact between ethnic groups reduces prejudice. If the communication takes the form of a threat, people may interpret the threat itself as a competitive response and become more likely to respond competitively (Gifford & Hine, 1997). Furthermore, the communication must be relevant. In one social dilemma study, cooperation increased only when people spoke openly about the dilemma and how they would be rewarded for various responses. Praising one another for past cooperation was most beneficial (Orbell, van de Kragt, & Dawes, 1988).

People can also communicate silently through the strategy they use. In the prisoner's dilemma game, the most effective strategy for producing long-term cooperation is to use basic learning principles and play *tit-for-tat.* This means rewarding cooperative responses with cooperation and punishing competitiveness by being competitive in return. Cooperating after a cooperative response and competing after a competitive response produces a high degree of cooperation over time (Nowak, May, & Sigmund, 1995; Zhong, Loewenstein, & Murninghan, 2007). But competing after a cooperative response may harm the relationship and threaten future cooperation (Monterosso et al., 2002). So players usually learn that the only way to come out ahead is to cooperate. There is even

evidence from computer simulation studies that societies whose members use cooperative strategies with one another are more likely to survive and prosper than societies whose members act competitively (Ginges et al., 2007; Nowak, May, & Sigmund, 1995).

Interpersonal Conflict

In social dilemmas and other situations in which people are *interdependent*—that is, when what one person does always affects the other—cooperation usually leads to the best outcomes for everyone. This is why social psychologists are applying research on cooperation to help people work more closely together in school, on the job, in the community, and even in efforts to protect the environment (van Vugt, 2009). Still, humans do not always cooperate. People from collectivist cultures, in which cooperation is emphasized, are generally less likely to act selfishly in a social dilemma, but conflict in such situations does occur in all cultures (Smith & Bond, 1999). Conflict is especially likely when people are involved in a **zero-sum game**. This is a situation in which one person's gains are subtracted from the other person's resources. It is called *zero-sum* because when you add up the gains and losses, the result is zero. Election campaigns, lawsuits over a deceased relative's estate, and competition between children for a toy are all examples of zero-sum games.

There are four major reasons that interpersonal conflicts can be difficult to resolve and why they may escalate (De Dreu, 2010). The first is that people in conflict invest so much time, effort, and commitment in establishing their own point of view that being asked to adjust it in order to compromise seems to be asking too much (Ku, Malhotra, & Murninghan, 2005). Second, people in interpersonal conflicts often see the problem as due to the other person's hostility or selfishness rather than to an honest difference of opinion (Samuelson & Messick, 1995). In other words, conflicts can become entrenched because of the actor-observer effect and other attributional errors discussed in the chapter on social cognition. So when the printer paper runs out at a crucial time, interpersonal conflict may escalate if the office manager—who was simply trying to cut paper costs—is perceived by other employees as being stingy and trying to make their lives miserable.

zero-sum game A social situation in which one person's gains are subtracted from another person's resources so that the sum of the gains and losses is zero.

Faulty communication is a third reason for the persistence of interpersonal conflicts. A comment intended as a compliment is sometimes interpreted as a snide remark, and constructive criticism is sometimes perceived as a personal attack. Such miscommunication can start a cycle of increasingly provocative actions in which each person believes the other is being aggressive and unfair (Pruitt & Carnevale, 1993). A fourth factor that can escalate interpersonal conflict is a tendency to believe that the other person is not really interested in reaching a settlement. This view may become a self-fulfilling prophesy (see the chapter on social cognition); each side may begin to behave in ways that actually bring about the uncooperative behavior expected from the other side, and the end result may be increasing conflict and eventually, a stalemate (Kennedy & Pronin, 2008).

Managing Conflict Interpersonal conflict can damage relationships among people and impair the effectiveness of organizations, but it can also lead to beneficial changes. Industrial and organizational psychologists have found that often it is much better to manage conflict effectively than to try to eliminate it. The most common way of managing organizational conflict is through *bargaining*. Each side—labor and management, for example—produces a series of offers and counteroffers until a solution emerges that is acceptable to both sides. At its best, bargaining can produce a win-win situation in which each side gets what is most important and gives up what is less important (Bacon & Blyton, 2007).

If bargaining fails, *third-party interventions* may be useful. Like a therapist working with a couple, an outside mediator can often help the two sides in an organizational conflict focus on important issues, defuse emotions, clarify positions and proposals, and make suggestions that allow each side to compromise without losing face (De Dreu, 2010).

Other techniques for managing conflict, especially conflict over resources, involve the introduction of *superordinate goals* or a *superordinate identity* (Abrams & Hogg, 2010). For example, if people who are competing for scarce resources can be made to feel that they are all part of the same group and share the same goals, they will act less selfishly and manage the limited resources more efficiently.

In short, although interpersonal conflict can be harmful if left unchecked, it can also be managed in a way that benefits the group. Much as psychotherapy can help people resolve personal conflict in a way that leads to growth, interpersonal conflict within an organization can be handled in a way that leads to innovations, increased loyalty and motivation, and other valuable changes.

Group Processes

Although Western industrialized cultures tend to emphasize individuals over groups, the fact remains that most important governmental and business decisions in those cultures and elsewhere are made by groups, not individuals (Hackman & Katz, 2010). Sometimes group processes are effective, as seen in the extraordinary teamwork of emergency workers and volunteers that led to dramatic rescues of people trapped in collapsed buildings after an earthquake struck Haiti in 2010. At other times, group processes can have disastrous results, as we will see later. In the chapter on cognition and language, we describe some of the factors that influence the nature and quality of group decisions. Here we consider some of the social psychological processes that often occur in groups to alter the behavior of their members and the quality of their collective efforts.

Group Leadership

A good leader can help a group pursue its goals; a poor one can get in the way of a group's functioning (Kaiser, Hogan, & Craig, 2008). What makes a good leader? Certain personality traits often distinguish effective leaders from ineffective ones. For example, using

A Different Kind of Coach

Many football coaches are task-oriented leaders whose tough discipline and emotional outbursts are legendary. Only a few, such as Tony Dungy, former coach of both the Indianapolis Colts and the Tampa Bay Buccaneers are charismatic leaders. Dungy's leadership style was calm and low-key; rather than shouting at his players, he inspired them to focus on his vision of success and to do their best to achieve it. Their love for him is evident here as Colts players carry Dungy off the field after winning the Super Bowl in 2007.

© Jeff Haynes/AFP/Getty Images

tests similar to those that measure the Big Five traits described in the chapter on personality, Colin Silverthorne (2001) examined the characteristics of leaders in the United States, Thailand, and China. He found that effective leaders in all three countries tended to score high on agreeableness, emotional stability, extraversion, and conscientiousness. Other researchers have found that in general, effective leaders are intelligent, success-oriented, flexible, and confident in their ability to lead (Chemers, Watson, & May, 2000; Foti & Hauenstein, 2007). Having particular personality traits does not guarantee good leadership ability, however. People can be effective leaders in one situation but ineffective in another (Ng, Ang, & Chan, 2008). The reason is that effective leadership also depends on the characteristics of the group members, the task at hand, and the interaction between these factors and the leader's style (Yun, Faraj, & Sims, 2005).

For many years, leadership research focused on two main types of leaders, known as *task-motivated* and *relationship-motivated*. **Task-motivated leaders** provide close supervision, lead by giving directives, and generally discourage group discussion (Yukl & Van Fleet, 1992). Their style may not endear them to group members. **Relationship-motivated leaders** provide loose supervision, ask for group members' ideas, and are generally concerned with subordinates' feelings. They are usually well liked by the group, even when they must discipline a group member (Kassin, Fein, & Markus, 2010).

More recently, some researchers have proposed that there are additional leadership styles. One of these is seen in *transactional leaders,* whose leadership behavior depends on the actions of the people they lead. For example, transactional leaders reward people who behave as the leader wishes, and they correct or punish those who behave otherwise. In contrast, there are also *transformational,* or *charismatic, leaders* (Hogg, 2010). Rather than focusing on rewarding or punishing specific behaviors, these leaders concentrate on creating a vision of the group's goals, inspiring people to pursue that vision, and giving their followers reason to respect and admire them. Transformational leaders such as Winston Churchill and Martin Luther King Jr. have dramatically changed the world for the better, and many less famous leaders of social or business groups have done the same on a smaller scale.

Do men or women make better leaders? Alice Eagly and her colleagues have studied differences between men and women in leadership styles (e.g., Eagly, Karau, &

task-motivated leader A leader who provides close supervision, leads by directives, and generally discourages group discussion.

relationship-motivated leader A leader who provides loose supervision, asks for group members' ideas, and is concerned with subordinates' feelings

Makhijani, 1995). Their initial research found that overall, men and women are equally capable leaders. It also seemed that men tended to be more effective when success required a task-motivated leader and that women tended to be more effective when success required a more relationship-motivated leader. In other words, it appeared that people of each sex tended to be most effective when acting in a manner consistent with gender-role traditions (Eagly & Karau, 1991; Eagly, Karau, & Makhijani, 1995). Perhaps this was because some people did not like female leaders who act in a "masculine" manner or occupy leadership positions traditionally held by men (Eagly, Makhijani, & Klonsky, 1992).

LINKAGES How does stress affect group decision making? (a link to Health, Stress, and Coping, p. 581)

A somewhat different picture of gender differences in leadership has emerged from Eagly's more recent research. For one thing, she found that females are generally more likely than males to display a transformational leadership style. Further, when women display a transactional style, they tend to be more encouraging than transactional male leaders. That is, the transactional female leaders tend to focus more on using rewards rather than punishments to modify group members' behaviors. Finally, and in contrast to earlier findings, Eagly's results suggest that women may be slightly more effective leaders overall than men, even though they may still face challenges in convincing some male followers to accept them as legitimate authorities (Ayman, Korabik, & Morris, 2009; Eagly & Sczesny, 2009).

Groupthink

The emphasis on group decisions in most large organizations is based on the belief that a group of people working together will make better decisions than individuals working alone. As noted in the chapter on cognition and language, this belief is generally correct; yet under certain circumstances, groups have been known to make amazingly bad decisions (Kassin, Fine, & Markus, 2010). Consider an example from 2003, when officials at the National Aeronautics and Space Administration (NASA) ignored engineers' warnings about the damage done to the heat shield of the space shuttle *Columbia* during its launch into orbit. Despite the engineers' repeated requests to use satellite photos to assess the extent of the damage, NASA officials approved the shuttle's return to earth without any inspections. Because of heat shield damage, the spacecraft disintegrated upon reentry, killing all seven crew members. Irving Janis (1989) proposed that disastrous decisions like this one can be attributed to a phenomenon called **groupthink**. Groupthink occurs, he said, when group members are unable to realistically evaluate the options available to them or to fully consider the potential negative consequences of the option they are considering. It is particularly likely when members of a group place a higher value on reaching a decision than on being sure they have reached the best decision.

Trying to reach a consensus before a group acts is not necessarily a bad strategy. In fact, it usually produces a good decision and positive feelings about the group (Smith & Mackie, 2007). But according to Janis, the drive toward consensus is likely to produce groupthink and bad decisions when four conditions are present: (1) the consensus is not based on all the facts at hand, (2) group members all share certain biases, (3) members who disagree with the majority view are punished or even ejected from the group, and (4) the group leader puts pressure on the members to reach consensus.

Some social psychologists believe that bad group decisions can be explained by processes other than groupthink (e.g., Baron, 2005; Hackman & Katz, 2010), but instances of groupthink probably do occur. With that in mind, researchers have worked on developing techniques to help groups avoid it (Galinsky & Kray, 2004; Kray & Galinsky, 2003; Packer, 2009). One way to avoid groupthink is to teach group members to imagine all the negative outcomes of each course of action they are considering. Another is to designate someone to take the unpopular role of "devil's advocate"—to constantly challenge the group's emerging consensus and offer alternatives. This person forces the group to consider all the facts and every possible decision option (Janis,

groupthink A pattern of thinking in which group members fail to evaluate realistically the wisdom of various options and decisions.

1985; Risen, 1998). Yet another technique is to encourage the expression of diverse opinions by allowing them to be presented anonymously. The group members might sit at computers and type out messages about all the options that occur to them. Each message is displayed for all to see on an electronic mail system that hides each sender's identity. This procedure allows the group to discuss the options via e-mail without knowing who is saying what. Research on this technique suggests that it is effective in stimulating logical debate and making people less inhibited about disagreeing with the group (O'Brien, 1991).

LINKAGES

As noted in the chapter on introducing psychology, all of psychology's subfields are related to one another. Our discussion of how the presence of other people affects a person's motivation to perform illustrates just one way in which the topic of this chapter, social influence, is linked to the subfield of motivation and emotion (see the chapter on that topic). The Linkages diagram shows ties to two other subfields as well, and there are many more ties throughout the book. Looking for linkages among subfields will help you see how they all fit together and help you better appreciate the big picture that is psychology.

SUMMARY

Social Influence

Social norms establish the rules for what should and should not be done in a particular situation. Descriptive norms indicate what most other people do and create pressure to do the same. Injunctive norms provide specific information about what others approve or disapprove of. *Deindividuation* is a psychological state in which people in a group temporarily lose their individuality, focus on the group's norms, and may engage in antisocial acts that they would not normally perform. *Social facilitation, social interference,* and *social loafing* provide three other examples of how the presence of other people can affect an individual's behavior.

Conformity and Compliance

When behavior or beliefs change as the result of unspoken or implicit group pressure, *conformity* has occurred; when the change is the result of a request, *compliance* has occurred.

The Role of Social Norms

People tend to follow the normative responses of others, and groups create social norms when none already exist.

Why Do People Conform?

People sometimes exhibit public conformity without private acceptance. At other times, the responses of other people have a genuine impact on private beliefs. People conform because they want to be right, because they want to be liked, and because they tend to be rewarded for doing so.

When Do People Conform?

People are most likely to conform when the situation is ambiguous or when others in the group are in unanimous agreement. Up to a point, conformity usually increases as the number of people holding the majority view grows larger. Persistent and unanimous *minority influence* can also produce some conformity.

Inducing Compliance

Effective strategies for inducing compliance include the foot-in-the-door technique, the door-in-the-face technique, and the low-ball technique.

Obedience

Obedience involves complying with an explicit demand, typically from an authority figure. Research by Stanley Milgram indicates that levels of obedience are high even when obeying an authority appears to result in pain and suffering for another person.

Factors Affecting Obedience

People obey someone who has certain kinds of social power. Obedience declines when the status of the authority figure declines, when others are observed to disobey, and if a victim asks to be released. Some people may be more likely to obey orders than others.

Evaluating Milgram's Studies

Because participants in Milgram's studies experienced considerable stress, the experiments have been questioned on ethical grounds. Nevertheless, Milgram's research showed that even apparently "normal" people can be influenced to inflict pain on others.

Aggression

Aggression is an act intended to harm another person.

Why Are People Aggressive?

Sigmund Freud viewed aggression as due partly to self-destructive instincts. More recent theories attribute aggressive tendencies to genetic factors, brain dysfunctions, and hormonal influences. Learning is also important. People learn to display aggression by watching others and by being rewarded for aggressive behavior. There are wide cultural differences in the incidence of aggression.

When Are People Aggressive?

A variety of emotional factors play a role in aggression. The *frustration-aggression hypothesis* suggests that frustration can lead to aggression, particularly if cues that invite or promote aggression are present. Recent research indicates that stress and negative feelings play a major role in aggression. Arousal from sources unrelated to aggression, such as exercise, can also make aggressive responses more likely. Research in *environmental psychology* suggests that factors such as high temperature, noise, and crowding increase the likelihood of aggressive behavior.

Altruism and Helping Behavior

Human behavior is also characterized by *helping behavior* (*prosocial behavior*) and *altruism*.

Why Do People Help?

There are three major theories as to why people help others. According to the *arousal: cost-reward theory,* people help in order to reduce the unpleasant arousal they experience when others are in distress. Their specific reaction to a suffering person depends on the costs associated with helping or not helping. Helping behavior is most likely when the costs of helping are low and the costs of not helping are high. Perceptions of cost are affected by the clarity of the need for help, the *bystander effect* (which creates diffusion of responsibility), and personality traits. Environmental factors also affect willingness to help. The *empathy-altruism theory* suggests that helping can be truly unselfish if the helper feels empathy for the person in need. Evolutionary theory suggests that humans have an innate tendency to help others, especially relatives, because doing so increases the likelihood that family genes will survive.

Cooperation, Competition, and Conflict

Cooperation is behavior in which people work together to attain a goal. *Competition* exists when individuals try to attain a goal while denying that goal to others. *Conflict* occurs when a person or group believes that someone stands in the way of something of value.

Social Dilemmas

In *social dilemmas,* selfish behavior that benefits individuals in the short run may spell disaster in the long run if adopted by an entire group. Two kinds of social dilemmas are seen in the *prisoner's dilemma game* and in resource dilemmas. When given a choice between cooperation and competition in a social dilemma, people often compete with one another. This is true even though they may receive fewer rewards for competing than for cooperating.

Promoting Cooperation

Communication between competing parties can increase cooperation, especially if the communication is not threatening and is relevant to the situation. One of the most effective strategies for producing long-term cooperation in a prisoner's dilemma game is rewarding cooperative responses with cooperation and punishing competitive responses with competitiveness.

Interpersonal Conflict

In *zero-sum games,* competition is almost inevitable because there can be only one winner. Incompatible interests, attribution of another's behavior to unfriendly motives, faulty communication, and magnification of differences are frequent sources of interpersonal conflict. Bargaining, third-party interventions, and reminders about broader goals and shared identity are helpful procedures for managing conflict.

Group Processes

Many of the most important decisions are made by groups.

Group Leadership

No single personality type or behavioral style always results in good leadership. *Task-motivated leaders* provide close supervision, lead by giving directives, and generally discourage group discussion. *Relationship-motivated leaders* provide loose supervision, ask for group members' ideas, and are generally concerned with subordinates' feelings. Transformational leaders try to inspire and motivate the group; transactional leaders tend to reward appropriate behaviors and punish inappropriate ones.

Groupthink

The pattern of thinking called *groupthink* can occur when the desire to reach a group decision becomes more important than the need to reach the best decision.

LINKAGES TO FURTHER LEARNING

Now that you have finished reading this chapter, how about exploring some of the topics and information that you found most interesting? Here are some places to start.

Books

Elliot Aronson, *Nobody Left to Hate* (Freeman, 2000). A social psychologist explores the social roots of the Columbine school massacre.

Hans-Werner Bierhoff, *Prosocial Behavior* (Psychology Press, 2002). An introductory overview of research on helping and altruism.

Robert Cialdini, *Influence: Science and Practice* (Addison-Wesley, 2007). Summary of research on influence and how it is applied in everyday life.

Russell Geen and Edward Donnerstein (Eds.), *Human Aggression: Theory, Research, and Implications for Social Policy* (Academic Press, 1998). Readings on the origins of and factors in aggression.

TALKING POINTS

Here are a few talking points to help you summarize this chapter for family and friends without giving a lecture.

1. Copycat crimes illustrate the fact that people's behavior can be influenced by the behavior of others.
2. In crowds where people feel they cannot be identified, they may do antisocial things that they might never do otherwise.
3. Having an audience can help our dancing or musical performance if our skills are well learned but can be disruptive if those skills are not yet well established.
4. Sometimes the best way to get someone to do something is to first ask for something else.
5. People who might not ordinarily harm another person can be influenced by social pressure—especially from an authority figure—to do some surprisingly antisocial things.
6. Aggressive behavior is shaped by both inherited tendencies and situational factors.
7. You are more likely to get help in an emergency if only one other person is present than if you are in a crowd.

SUMMARY

If you have a full-time or part-time job, you know that workdays blend demands, challenges, difficulties, and rewards—all of which can affect job satisfaction. Understanding the causes and effects of job satisfaction is just one aspect of industrial and organizational (I/O) psychology, the topic of this chapter. We will describe how I/O psychologists conduct their research and how they apply that research to improve the performance and welfare of workers and of the organizations that employ them.

Suppose that you are the manager of a department store. You want to hire someone to head up the cosmetics department, but you are not sure how to choose the best person for the job. Should you rely on interviews with each of the candidates, or should you also give them some psychological tests? Perhaps you decide to do both, but what questions should you ask during the interviews? What kinds of tests should you use? And how should you interpret the results? Further, what happens after you make your hiring decision? Do you have procedures available to train, motivate, supervise, and reward employees so that they perform at their best and are happy in their work? For answers to questions like these, many human resource managers and other company executives seek the help of *industrial and organizational* (*I/O*) *psychologists.* We briefly mentioned I/O psychology in the chapter on introducing psychology; here we describe it more detail, including a summary of what I/O psychologists do and some of the ways that their work benefits organizations and employees.

An Overview of Industrial and Organizational Psychology

We have said that psychology is the science of behavior and mental processes. The subfield of **industrial and organizational (I/O) psychology** is the science of behavior and mental processes in the workplace. Industrial and organizational psychologists conduct scientific research on all sorts of people-oriented workplace topics, such as what personality traits predict good performance under stress and what social factors cause conflict in work groups. I/O psychologists are also hands-on practitioners who help organizations apply research findings to problems such as matching employees to jobs and maximizing cooperation in workplace teams. The link between scientific research and professional practice can be especially strong in I/O psychology because the workplace provides both a natural laboratory for studying psychological questions and a setting in which research-based answers can be applied and evaluated.

Industrial and organizational psychologists address two main goals in their research and practice. The first is *promoting effective job performance* by employees, which ultimately leads to enhanced performance by the organization as a whole. The second goal is to contribute to human welfare by *improving the health, safety, and well-being of employees.* This second goal is important in itself but is also related to the first one. In effective organizations, employees are not only capable of performing their jobs well but are also healthy and well adjusted in the workplace.

Industrial and organizational psychology emerged early in the 1900s as psychologists began to apply laboratory-based principles of learning, memory, and motivation to solve practical problems in the workplace. Over the years, research and applications in I/O psychology have continued to be influenced by laboratory research in many

industrial and organizational (I/O) psychology The science of behavior and mental processes in the workplace.

Teaching I/O Psychology

Some graduates pursue careers in I/O psychology after completing a master's degree, but salaries and opportunities are better for those with a Ph.D. For example, virtually all I/O psychologists who are hired as college or university professors have completed a doctoral degree. Master's or doctoral training in I/O psychology is available at more than one hundred universities in the United States, ten in Canada, and more than eighty in other countries (Society for Industrial and Organizational Psychology, 2007; for more information on these programs, visit www.siop.org).

of psychology's subfields, including cognitive psychology, personality, motivation and emotion, health psychology, and especially social psychology. The work of I/O psychologists is also shaped by findings in other fields, including business management, engineering, and medicine.

Like psychologists in other subfields, I/O psychologists hold graduate degrees in their specialty. The popularity of the I/O specialty has grown rapidly in recent decades, both in North America and throughout the industrialized world (Spector, 2003). According to a survey by the Society for Industrial and Organizational Psychology, about 41 percent of I/O psychologists are employed as professors in college or university departments of psychology, business, or related fields. Another 24 percent own or work in consulting firms that provide services to private and public organizations on a fee-based freelance basis. About 24 percent are hired as technical specialists by private corporations, and about 7 percent act as research scientists in the public sector, including in government agencies (Khanna & Medsker, 2007). Let's consider some of the specific kinds of work that I/O psychologists do in these various settings.

Assessing People, Jobs, and Job Performance

If you apply for a job with a large corporation or government agency, you will probably be asked to take one or more standardized tests of personality or mental ability and to participate in other assessments whose results will help determine whether you will fit well into the organization and have the "right stuff" for the job you seek. Organizations commonly turn to I/O psychologists to design or conduct these assessment programs, so one of the main areas of scientific research in I/O psychology is the development and evaluation of new and better assessment devices.

Knowledge, Skills, Abilities, and Other Characteristics

Industrial and organizational assessments are often used to identify the human attributes necessary for doing jobs successfully. Those attributes are referred to collectively as *KSAOs*, which stands for knowledge, skill, ability, and other personal characteristics. *Knowledge* refers to what the person already knows. *Skill* refers to how well a person does a particular task. *Ability* is defined as the person's relatively enduring capacities in areas such as thinking, physical coordination, and the like. Skills and abilities are closely related; some researchers consider skills to be the products of inherent abilities (Muchinsky, 2003). *Other personal characteristics* can be almost anything else about a person, including attitudes, personality traits, physical characteristics, preferences, and values.

Job Analysis

How do organizations know which KSAOs are important for which jobs? The answer lies in **job analysis**, in which I/O psychologists collect information about particular jobs and job requirements. This job analysis information is then used to guide decisions about whom to hire and what kind of training is needed to succeed at a particular job (Brannick & Levine, 2002; Krause & Thornton, 2009).

There are three major approaches to job analysis. The *job-oriented approach* focuses on the tasks involved in doing a job, such as wiring circuit boards, creating a computer database, or driving a truck. The *person-oriented approach* focuses on the KSAOs needed to do those job tasks (see Table 19.1). The *personality-oriented approach* focuses on the specific personality characteristics associated with success in a job. Most job analyses take either the job-oriented or person-oriented approach, but the personality-oriented approach is often used by organizations in which high-quality customer service is of great importance (Aguinis, Mazurkiewicz, & Heggestad, 2009). A job analysis report can be a relatively superficial description, a microscopically detailed examination, or anything in between. The approach taken and the level of detail included in a job analysis depend mainly on how the report will be used. When the analysis will guide the hiring of employees, it should contain enough detail to make it clear what a particular job requires and to show—in a court of law, if necessary—how the selection process is related to the requirements established by the job analysis. The person-oriented approach is the most useful one for this purpose because it describes the KSAOs that the employer should be looking for in the new employee.

Job analysis can also help organizations recognize the need to train employees, and it can even outline the kind of training required. Suppose that you have five job openings, but when you test candidates for hiring or promotion, too few of them possess the KSAOs that a job analysis says are necessary for success in these positions. Obviously, some training will be needed, and because the job analysis lists specific KSAOs, you can use that analysis to determine exactly what the training should include. Suppose that a job analysis reveals that people in a computer sales position must be familiar with the Linux operating system. As a result, you would provide Linux training for all individuals hired for that position unless they already knew that operating system.

The most common method of job analysis is to ask current employees (known as *job incumbents*) to fill out questionnaires about what they do in the workplace. However, a somewhat more reliable picture may emerge when specially trained job analysts observe people as they do their jobs or even perform those jobs themselves (Dierdorff & Wilson, 2003). If the goals of job analysis include comparing one job to another, I/O psychologists might use an instrument such as the Position Analysis Questionnaire, or PAQ (McCormick, Jeanneret, & Mecham, 1972). The 189 items on the PAQ can describe almost any job in terms of a particular set of characteristics, or dimensions, such as the degree to which a job involves communicating with people, lifting heavy objects, or doing mental arithmetic. The results of thousands of job analyses have been

job analysis The process of collecting information about jobs and job requirements that is used to guide hiring and training decisions.

TABLE 19.1 Knowledge, Skill, Ability, and Other Characteristics (KSAOs)

Here are examples of the kinds of KSAOs required for successful performance by people working in two different jobs.

Job Title	Knowledge	Skill	Ability	Other
Secretary	Knowledge of office procedures	Skill in using a word-processing program	Ability to communicate with others	Willingness to follow instructions
Plumber	Knowledge of county building codes	Skill in using a wrench	Good hand-eye coordination	Willingness to work in dirty environments

collected in the U.S. Department of Labor's Occupational Information Network, or O*NET (Peterson et al., 2001). This electronic database contains analyses of approximately eleven hundred job categories, including the KSAOs and tasks involved in each and how each job fits into its organizational context. Accessible online at online.onetcenter.org, O*NET is an excellent source of information about occupations for anyone who is in the process of choosing a career. You might want to visit the site yourself; you may find descriptions of jobs you have never before considered pursuing.

Measuring Employee Characteristics

LINKAGES What methods are used to select good employees? (a link to Personality, p. 588)

I/O psychologists use a wide variety of instruments to measure a person's knowledge, skill, ability, and other characteristics. These instruments range from simple paper-and-pencil tests—perhaps an arithmetic test for a sales clerk—to several days of hands-on activities that simulate the tasks required of a midlevel manager. Some assessments are used to select new employees, others are designed to choose employees for promotion, and still others are meant to determine how well employees are doing their jobs at the moment. The three main methods to measure employee characteristics are psychological tests, job applicant interviews, and assessment center exercises.

Psychological Tests A *psychological test* is a systematic procedure for observing behavior in a standard situation and describing it on a number scale or a system of categories (Anastasi & Urbina, 1997). Some tests present a standardized series of problems or questions, each of which has one correct answer, much like the multiple-choice exams used in some college classrooms. Others are more like essay exams in which the respondent is asked to, say, describe an ideal sales organization. These essay-type exams are not scored by a computer but by experts who use job analysis information and their own job experience to judge the correctness or quality of the responses. Still other tests require the respondent to demonstrate skill by performing a task such as typing a letter, debugging a computer program, repairing a car, or giving a sales talk.

The tests I/O psychologists most often use to measure general mental ability and skill are the standard intelligence tests described in the cognitive abilities chapter. These tests are relatively inexpensive and easy to administer, and they do a reasonably good job of predicting how well people will do on a wide variety of occupational tasks (Bertau, Anderson, & Salgado, 2005; Jansen & Vinkenburg, 2006; Rooy et al., 2006). In addition, job applicants might be asked to participate in *situational judgment tests* (*SJTs*) in which they read about or view videos of various workplace situations, such as a conflict between coworkers. The applicants are then asked to rate which of several responses to that situation would be best or to describe what they would do if confronted with that same situation (Sackett & Lievens, 2008). The information provided by SJTs supplements cognitive and personality tests and provides an additional perspective from which to predict an applicant's eventual job performance (Lievens, Peeters, & Schollaert, 2008; Salter & Highhouse, 2009). Tests of job-relevant knowledge—such as basic accounting principles or stock-trading rules and regulations—may also be used to confirm that an individual has the information necessary to succeed at a particular job. Finally, personality tests are used to assess a wide variety of other employee characteristics. As described in the personality chapter, some of these tests provide information about personality dimensions that may be relevant to hiring decisions. For example, a person's score on *conscientiousness* (i.e., reliability and industriousness) has been linked to job performance in many occupations (Dudley et al., 2006; Meyer, Dalal, & Bonaccio, 2009; Thoresen et al., 2003). Personality-related *integrity tests* are sometimes used to identify people who have tendencies that might lead them to steal or engage in dangerous or disruptive acts (Berry, Sackett, & Wiemann, 2007; Casillas et al., 2009; Ones & Viswesvaran, 2001). These are usually paper-and-pencil tests that ask respondents about their thoughts or temptations regarding theft, their perceptions of norms regarding dishonesty, their own social conformity, and their history of associating with delinquents (Wanek, Sackett, & Ones, 2003).

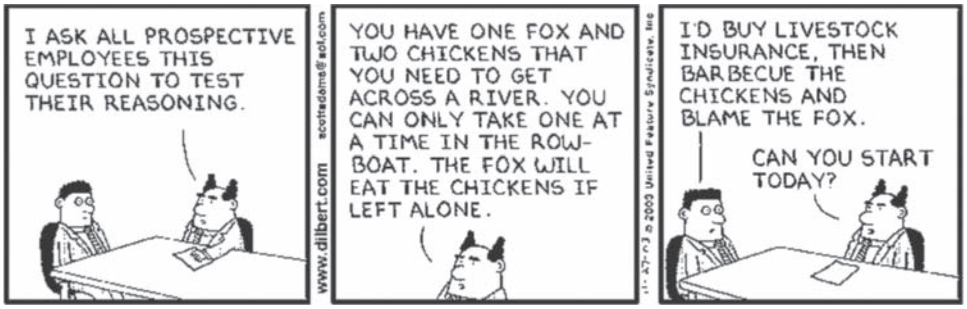
A Matter of Degree

When hiring employees for some jobs, organizations often rely on credentials rather than knowledge tests. For example, an undergraduate degree in any major may be enough to qualify for some white-collar jobs because it is assumed that college graduates have enough general knowledge and "mental horsepower" to succeed. For jobs in medicine, law, accounting, engineering, and other specialty fields, candidates' knowledge is assumed if they have completed a particular degree program or earned a particular license. These assumptions are usually correct, but credentials alone do not always guarantee competence.



I ASK ALL PROSPECTIVE EMPLOYEES THIS QUESTION TO TEST THEIR REASONING.
YOU HAVE ONE FOX AND TWO CHICKENS THAT YOU NEED TO GET ACROSS A RIVER. YOU CAN ONLY TAKE ONE AT A TIME IN THE ROW-BOAT. THE FOX WILL EAT THE CHICKENS IF LEFT ALONE.
I'D BUY LIVESTOCK INSURANCE, THEN BARBECUE THE CHICKENS AND BLAME THE FOX.
CAN YOU START TODAY?

Conducting structured interviews ensures that each prospective employee will be asked about the things that are most important to the employer when filling a job. It is easy to see what kind of workers this boss is seeking.

Job Applicant Interviews *Job applicant interviews* are designed to determine an applicant's suitability for a job. Interviews usually take place in person, though some are conducted by telephone, videoconferencing, or even e-mail. As mentioned in the personality chapter, interviews can be structured or unstructured (open-ended). In a *structured interview,* the interviewer has prepared a list of specific topics or even specifically worded questions to be covered in a particular order (Chapman & Zweig, 2005). In *unstructured interviews,* the course of the conversation is more spontaneous and variable. Following some interviews, especially structured interviews, the candidate's responses will be rated on a set of dimensions such as product knowledge, clarity of expression, and poise. After other interviews, the interviewer's subjective impression of the candidate is used to make a yes-or-no judgment about the candidate's suitability for the job.

Research consistently shows that structured interviews are far more effective than unstructured interviews in leading to good hiring decisions (e.g., Huffcutt & Arthur, 1994). The difference is due largely to the fact that structured interviews focus specifically on job-related knowledge and skills, especially interpersonal skills, whereas unstructured interviews do not (Huffcutt et al., 2001). Further, lack of structure makes it easier for personal bias to enter the hiring picture. Ratings from an unstructured interview might have more to do with the interviewer's personal bias about the candidates' appearance and presentation style than with the candidates' objective qualifications (Barrick, Shaffer, & DeGrassi, 2009). There is some evidence that job candidates tend to prefer interview-based assessments over test-based assessments. This preference is of interest, especially when competing for top candidates, because those who have positive views of the selection process are more likely to like the organization and to accept a job offer (Hausknecht, Day, & Thomas, 2004).

Assessment Centers An **assessment center** is an extensive set of exercises designed to determine an individual's suitability for a particular job. Assessment centers are often used to hire or promote managers, but they can be employed in relation to other positions as well. A typical assessment center consists of two to three days of exercises that simulate various aspects of a job and that are rated by a team of judges, usually psychologists or specially trained managers (e.g., Gibbons & Rupp, 2009; Spychalski et al., 1997). Because assessment centers allow live observation of applicants' reactions in a variety of realistic work situations, they provide information about specific aspects of behavior that might not emerge from a test or an interview (Gibbons & Rupp, 2009).

The *in-basket* is a typical assessment center exercise for managers. Candidates are seated at a desk and asked to imagine that they have just taken over a new management job. On the desk is the previous manager's overflowing in-basket, containing correspondence, memos, phone messages, and other items. The candidate's task is to go through all this material and write on the back of each item what action should be taken to deal with it and when. Later, experts read what the candidate has written and assign an appropriateness score to each action. For example, candidates who prioritize tasks well—taking immediate action on critical matters and delaying action on less important ones—would receive higher scores than those who, say, deal with each task in the order in which it is encountered regardless of its importance.

assessment center An extensive set of exercises designed to determine an individual's suitability for a particular job.

Other assessment center exercises tap interpersonal skills. The job candidate might be asked to play the role of a manager who is working with others to solve a problem or who must discipline a problem employee. As in the in-basket task, each candidate is given a score by each judge on the knowledge, skills, abilities, and other job-related characteristics displayed during each exercise. Later, the evaluation team meets to arrive at a group evaluation, using total scores from all assessment center exercises to classify individuals in terms of their suitability for a particular position.

There is considerable evidence to support the value of assessment centers (Arthur et al., 2003; Jansen & Vinkenburg, 2006; Meriac et al., 2008). For example, the assessment center scores earned by first-year college students predicted their performance as teachers several years after graduation (Shechtman, 1992). Assessment centers have also successfully predicted the performance of police officers, pilots, and managers, among others (Dayan, Kasten, & Fox, 2002; Lievens et al., 2003; McEvoy & Beatty, 1989). Assessment centers can be expensive and time-consuming, though, and their results sometimes add little beyond what can be determined from an applicant's performance on interviews and cognitive tests. With these factors in mind some researchers suggest using assessment centers only as a second step in the selection process and only for applicants whose interview and test scores are neither high enough nor low enough to guide a final hiring decision (Dayan, Fox, & Kasten, 2008).

Measuring Job Performance

Almost all employees of medium to large organizations receive an annual **job performance** appraisal, which, much like a student's report card, provides an evaluation of how well they are doing in various aspects of their work. Organizations use job performance appraisals to guide decisions about employee salary raises and bonuses and about retention, promotion, and firing. The appraisals are also used to give employees feedback on the quality and quantity of their work (Rynes, Gerhart, & Parks, 2005). The feedback function of job performance appraisals is important because it helps employees recognize what they are doing right and what they need to do differently to reach their own goals and to promote the goals of the organization.

Establishing Performance Criteria One of the most important roles for I/O psychologists in designing job performance appraisal systems is to establish *criteria,* or benchmarks, that define what the organization means by "good" or "poor" performance (see Table 19.2). These criteria can be theoretical or actual. A *theoretical criterion* is a statement of what we mean by good or poor performance in theory. A theoretical criterion for good teaching, for example, might be "promotes student learning." This criterion certainly sounds reasonable, but notice that it does not specify how we would measure it in order to decide if a particular teacher is actually promoting student learning. So we also need an *actual criterion,* which specifies what we should measure to determine if the theoretical criterion has been met. An actual criterion for good teaching might be defined in terms of students' performance on a standardized test of what their teacher has taught them. If, on average, the students reach or exceed some particular score, the teacher will have satisfied one of the school district's criteria for good teaching.

Keep in mind, though, that the match between theoretical criteria and actual criteria is never perfect. The actual criterion chosen should provide a sensible way to assess the theoretical criterion, but the actual criterion may be flawed. For one thing, actual criteria are usually incomplete. There is probably more to good teaching, for example, than just ensuring that students attain a particular score on a particular test. The teacher may have done a great (or poor) job at teaching material that did not happen to be covered on that test. Second, factors other than the employee's performance can affect the actual criterion. Perhaps students' scores on a standardized test were affected partly by the work of a good (or poor) teacher they encountered before

job performance A measure of how well employees are doing in various aspects of their work, usually recorded annually.

TABLE 19.2 Examples of Theoretical and Actual Criteria

Here are some theoretical and actual criteria for several kinds of jobs. Notice that theoretical criteria tend to be rather vague, so for purposes of job performance appraisals, they must be backed up by actual criteria. By evaluating employees on how well they have reached actual criteria, organizations can decide whether the theoretical criteria have been met and can act accordingly.

Job	Theoretical Criterion	Actual Criterion
Architect	Design buildings	Number of buildings designed
Car salesperson	Sell cars	Number of cars sold per month
Police officer	Fight crime	Number of arrests made per month
Roofer	Install roofs	Square feet of shingles installed per month
Scientist	Make scientific discoveries	Number of articles published in scholarly journals

their current teacher was hired. I/O psychologists are sensitive to these problems, and they usually recommend that job performance appraisals be based on several actual criteria, not just one.

Methods of Performance Appraisal

The information used in job performance appraisals can come from objective measures and subjective measures.

Objective Measures *Objective measures* of job performance include counting the frequency of particular behaviors or the results of those behaviors. The number of calls made by a telemarketer, the number of computers shipped out by a factory worker, and the total value of items sold per month by a shoe store employee are just three examples of objective measures of job performance. Other objective measures might include records about the number of days employees are absent from work, how often they are late for work, or the number of complaints that have been filed against them (Roth, Huffcutt, & Bobko, 2003). Objective appraisal measures are especially valuable because they provide a close link between theoretical and actual performance criteria. If the theoretical criterion for good performance as a salesperson is to sell a company's products, the most closely linked actual criterion would be an objective count of the number of those products sold per month.

Objective methods of job performance are not right for all jobs, however, because some performance criteria cannot be evaluated by counting things. For example, it would make no sense to evaluate a teacher's job performance by counting the number of students taught per year. Teachers usually have no control over their class size, and in any case, an enrollment count tells us nothing about what the students learned. In other words, except for the simplest jobs, objective measures may fail to assess all the aspects of performance that are of interest to an organization. A salesperson may have sold twenty cars last month, but it would also be important to know how this was accomplished. If the person used high-pressure tactics that harmed the organization's reputation, the sales count tells only part of the story of this employee's performance. Similarly, this month's top salesperson may have done well only after inheriting a territory full of loyal customers who buy the company's products no matter what.

Subjective Measures No wonder, then, that I/O psychologists sometimes recommend that objective performance measures be supplemented, or sometimes even replaced, by subjective measures (Rynes, Gerhart, & Parks, 2005). *Subjective measures* of job performance take the form of a supervisor's judgments about various aspects of an employee's work, including overall level of performance, consistency of performance from day to day, and longer-term positive or negative performance trends (Reb & Greguras, 2010). Typically, the supervisor records these judgments on a graphic rating form or a behavior-focused rating form.

FIGURE 19.1

A Graphic Rating Form Used in Subjective Job Performance Appraisal

Supervisors often use graphic rating forms such as this one in subjective job performance appraisals. The ratings are based on the supervisor's personal experience with the employee and on subjective impressions of that employee's work.

Rate employee on each dimension on the left by checking the appropriate box corresponding to the level of performance for the past year.

Dimension	**Poor**	**Fair**	**Satisfactory**	**Above satisfactory**	**Outstanding**
Customer service					
Management of time					
Professional appearance					
Teamwork					
Work quality					
Work quantity					

Graphic rating forms list several criterion-related dimensions of job performance and provide a space for the supervisor to rate each employee's performance on each dimension, using a scale ranging from, say, 1 to 10 or from poor to outstanding (see Figure 19.1). These graphic ratings can be valuable, but they do reflect the supervisor's subjective judgment. And as in unstructured interviews, factors other than the employee's performance can influence the results (Wong & Kwong, 2005). For example, most graphic ratings are affected by *leniency error,* meaning that supervisors tend to use only the top of the scale. As a result, almost all employees in most organizations receive ratings that are "satisfactory" or better. Many supervisors also show errors based on the *halo effect,* meaning that they tend to give the same rating on every dimension of job performance. So if Tasha receives an "outstanding" rating on one dimension, she will probably be rated at or near "outstanding" on all the others. Similarly, if Jack is rated as only "satisfactory" on one scale, he will probably get "satisfactory" ratings on the rest of them.

To some extent, these "errors" reflect reality. After all, most people try to do their jobs well, and they may do about equally well (or equally poorly) in various aspects of their work (Balzer & Sulsky, 1992; Solomonson & Lance, 1997). However, when using graphic rating forms, supervisors may not carefully discriminate aspects of job performance that are satisfactory from those that need improvement. Further, many tend to go easy on their employees, especially if they like the employees (Ferris et al., 1994) or if other factors such as "political correctness" are operating in the situation (Tziner, Murphy, & Cleveland, 2005). This kind of bias can result in favoritism in which supervisors intentionally inflate ratings beyond what an employee's performance deserves (Fried & Tiegs, 1995; Rynes, Gerhart, & Parks, 2005). Supervisors who are biased against certain employees on ethnic or other grounds may give those employees undeservedly low ratings (Heilman & Haynes, 2008; Stauffer & Buckley, 2005). The operation of such biases can lead to employee dissatisfaction with the entire performance appraisal process (Ferris & Treadway, 2008).

To help minimize the errors and bias associated with graphic rating forms, I/O psychologists developed *behavior-focused rating forms,* which ask supervisors to rate employees on specific behaviors rather than general dimensions of performance (Smith & Kendall, 1963). These forms contain lists of *critical incidents* that illustrate different levels of performance—from extremely effective to extremely ineffective—on important job dimensions (Flanagan, 1954). A critical incident list relating to customer relations, for example, might include "listens patiently," "tries to reach a compromise," "coldly states store policy," and "angrily demands that complaining customers leave."

Once these behavior-focused forms are constructed, supervisors choose which incidents are most typical of each employee.

Behavior-based rating forms help supervisors and their employees come to a better understanding of what constitutes good and poor performance. Somewhat surprisingly, however, these forms do not appear to eliminate supervisor bias and error (Bernardin & Beatty, 1984; Latham et al., 1993). Accordingly, some employers assess employees' job performance on the basis of ratings by peers and subordinates as well as supervisors. These "360-degree" ratings are designed to provide a broader and potentially less biased picture of an employee's performance (Oh & Berry, 2009). ("In Review: Assessing People, Jobs, and Job Performance" summarizes our discussion of these topics.)

IN REVIEW Assessing People, Jobs, and Job Performance

Target of Assessment	Typical Purpose	What Is Assessed	Examples
Employees	Employee selection	Knowledge, skill, ability, and other personal characteristics (KSAOs)	Tests of ability, achievement, or personality; structured or unstructured interviews; assessment centers requiring simulated job tasks
Jobs	Matching employees to jobs; identifying training needs	Job tasks and personal attributes needed for the job	Job-oriented analysis (identifies required tasks); person-oriented analysis (identifies KSAOs required for success); personality-oriented analysis (focuses on specific personality characteristics associated with success)
Job performance	Feedback on performance; decisions about retention, salary adjustments, or promotion	Work activities or products; supervisors' reports	Evaluating employees' work in relation to theoretical and actual criteria as measured by objective (counting) or subjective (rating) methods

1. **Lists of critical incidents are contained in ____________ -focused employee rating forms.**
2. **An employer might use a two-day ____________ to measure your skill at the job you want.**
3. **In general, ____________ interviews are more useful in employee selection than ____________ interviews.**

Recruiting and Selecting Employees

We have described a number of assessment methods developed by I/O psychologists to help organizations hire, train, and evaluate employees. Let's now consider the role of I/O psychology in finding candidates for employment and in selecting the right people for each job.

Recruitment Processes

It is generally agreed that people are an organization's most valuable assets, because it is people who are ultimately responsible for success in achieving an organization's goals. Accordingly, there is often intense competition among organizations to recruit the "best and brightest" employees. It is a disciplined competition, however. There is no point in hiring this year's top ten accounting graduates if your organization only needs two new accountants. So the first step in effective recruiting is to determine what employees are needed and then to go after applicants to meet those needs.

Determining employment needs means more than just counting empty chairs. Analyses by I/O psychologists help organizations determine how many people in each position are needed at the moment and how many will be needed in the future. Suppose that a computer company anticipates a 20 percent growth in business over the next five years. That growth will require a 20 percent increase in the number of customer service representatives, but how many new representatives should be hired each month? An I/O psychologist's analysis would help answer this question. The analysis would take into account the growth projections as well as estimates of how many representatives quit each year and whether the existing ratio of customer service employees to customers is too high, too low, or about right for efficient operation. In making recommendations about recruitment plans, I/O psychologists must also consider the intensity of demand for employees in various occupations. More active recruitment plans will be necessary to attract the best people in high-demand areas (see Table 19.3).

Once employment needs are established and the competitive landscape has been explored, the next step in recruitment is to persuade people with the right kinds of knowledge, skill, ability, and other characteristics to apply for the jobs to be filled. The six most common methods for identifying and attracting candidates are (1) newspaper advertising; (2) posting jobs on hotjobs.com, Monster.com, or other recruitment

TABLE 19.3 Fast-Growing Occupations

Here are the twenty fastest-growing occupations according to the U.S. Bureau of Labor Statistics (2008a). Industrial and organizational psychologists must take such trends into account when making recommendations about where to make the strongest efforts at recruiting new employees. (For more information about these job categories, see U.S. Bureau of Labor Statistics, 2006, 2008b, available online at www.bls.gov/emp/optd).

Occupation	Projected Employment Change, 2006–2016 (%)
Network systems and data communications analysts	53.4
Personal and home care aides	50.6
Home health aides	48.7
Computer software engineers, applications developers	44.6
Veterinary technologists and technicians	41.0
Personal financial advisers	41.0
Makeup artists, theatrical and performance artists	39.8
Medical assistants	35.4
Veterinarians	35.0
Substance abuse and behavioral disorder counselors	34.3
Skin care specialists	34.3
Financial analysts	33.8
Social and human service assistants	33.6
Gaming surveillance officers and gaming investigators	33.6
Physical therapist assistants	32.4
Pharmacy technicians	32.0
Forensic science technicians	30.7
Dental hygienists	30.1
Mental health counselors	30.0
Mental health and substance abuse social workers	29.9

Web sites; (3) interviewing graduating seniors on college campuses; (4) collecting information from current employees about potential candidates; (5) working with employment agencies, recruiting consultants, and private "headhunting" firms; and (6) accepting walk-in applications from job seekers who appear on their own. The recruitment methods used for any particular job will depend on how easy or difficult it is to attract high-quality applicants and on the importance of the position in the organization. For relatively low-level positions requiring few skills, it may be possible to rely on walk-in applicants to fill available positions. Much more effort and a variety of recruitment methods may be required to attract top-notch candidates for higher-level jobs that demand extensive experience and skill.

Selection Processes

Selecting the right employee for a particular job is generally a matter of using tests, interviews, and assessment centers to find the best fit between each candidate's characteristics and the tasks and characteristics that a job analysis identified as necessary for successful performance. This matching strategy would suggest that a candidate who is better at written communication than at computer skills would do better in, say, the marketing department than at the computer help desk.

Is this strategy the best way to select employees? Usually it is, but I/O psychologists help ensure that the characteristics identified as predicting success at particular jobs are in fact associated with success. To do this, they conduct **validation** studies, which are research projects designed to determine how well a particular test, interview, or other assessment method predicts an employee's job performance (Chan, 2005). For example, on the basis of a job analysis conducted many years ago, a department store might require applicants for sales clerk positions to pass a test of mental arithmetic. A validation study could determine whether scores on that test are actually related to sales clerks' performance. The easiest way to conduct this study would be to ask a representative sample of the store's current sales clerks to take the arithmetic test. A correlation coefficient would then be computed that describes the relationship between their test scores and some objective or subjective performance criterion, such as monthly sales figures or a supervisor's ratings. If those who score highest on the mental arithmetic test also do best at their jobs, the test can be considered valid for predicting job performance. If not, it may be that for clerks using today's computerized sales terminals, mental arithmetic is no longer as important to job success as it was in the past.

A large body of results from I/O psychology research is available to tell organizations which types of tests and other assessments are valid in predicting performance in which types of jobs. This database saves organizations a great deal of time and money because it eliminates the need to conduct their own validation studies for each assessment device they use in selecting employees for every job they want to fill.

Legal Issues in Recruitment and Selection

The United States and many other industrialized countries have established the principle that hiring, firing, and promotion processes should not discriminate against anyone on the basis of characteristics that have nothing to do with job performance. This principle has been translated into laws designed to protect all employees and job candidates against unfair discrimination. U.S. laws have also identified and created special safeguards for several *protected classes*—including women, Asians, blacks, Hispanics, American Indians, and other groups whose members have been discriminated against in the past. Together, these laws make it illegal for employers in the United States to discriminate in hiring or promotion on the basis of a candidate's age, ethnicity, gender, national origin, disability, or religion. In some states and in some other countries, discrimination on the basis of sexual orientation is also prohibited.

validation In I/O psychology, the effort to determine how well a test, interview, or other assessment method predicts job performance.

Ensuring Equal Opportunity

Affirmative action (*AA*) is an important element of the U.S. government's *Uniform Guidelines on Employee Selection Procedures*. A major goal of AA was to encourage organizations to actively seek job applicants from underrepresented minority groups and in the process ensure that qualified minority candidates are not overlooked. Critics claim, though, that AA establishes quota systems in which certain percentages of people from particular groups must be hired or promoted, even if they are not all well qualified. AA has thus become an increasingly controversial aspect of employment law.

© Comstock/Jupiterimages

In 1978, I/O psychologists helped the U.S. government create its *Uniform Guidelines on Employee Selection Procedures,* a document that outlines the steps organizations must take to ensure fairness in hiring and promotion. (You can review this document at www.uniformguidelines.com/uniformguidelines.html.)

The most important element of these guidelines is the requirement that personnel decisions be based solely on job-related criteria. This means that in choosing new employees, for example, organizations should hire those whose knowledge, skill, ability, and other characteristics match the KSAO requirements previously established by the job analysis process described earlier. The guidelines also state that organizations should use only test scores and other assessment data that validation studies have established as good predictors of job performance.

Training Employees

Every year, organizations in the industrialized world spend billions on training their employees (Thompson et al., 2002); the figure is more than $126 billion each year in the United States alone (Paradise, 2007). I/O psychologists are often directly involved in identifying the need for training, in designing training methods and content, and in evaluating the outcome of training efforts. Some I/O psychologists actually conduct training programs, but in most cases, these programs are delivered by professional trainers.

Assessing Training Needs

To help organizations identify which employees need what kind of training, I/O psychologists typically carry out a *training needs assessment* that takes into account the organization's job categories, workforce, and goals (Goldstein, 1993). One aspect of this assessment is to look at job analysis reports. As mentioned earlier, the need for training is indicated when job analyses reveal that certain jobs require KSAOs that employees do not have or that could be strengthened. A second aspect of a training needs assessment is to give employees a chance to describe the training they would like to have. This information often emerges from *personal development plans* that employees and their supervisors create. These plans usually include an evaluation of the person's strengths and weaknesses. The weaknesses suggest where training might be useful, especially for employees who are motivated to improve their skills (Klein, Noe, & Wang, 2006). For example, if the supervisor notes that an individual is awkward when making presentations, a course in public speaking might be worthwhile. Finally, the I/O psychologist will look at the goals of the organization. If those goals include reducing workplace accidents or improving communication with international customers, training in safety procedures or foreign language skills would be in order.

Designing Training Programs

In designing training programs for use by organizations, I/O psychologists are always mindful of the basic principles that govern the learning and remembering of new information and skills. These principles, which are described in the learning and memory chapters, guide efforts to promote *transfer of training, feedback, training in general principles*, *overlearning,* and *sequencing.*

Transfer of Training The most valuable training programs are those that teach knowledge and skills that will generalize, or transfer, to the workplace. If employees don't see how to apply what they have learned so as to improve their job performance, the training effort will have been wasted. Because promoting *transfer of training* is not always easy, I/O psychologists develop written materials and active-learning exercises that not only clarify the link between training and application but also give employees a chance to apply new knowledge and skills in simulated work situations. So trainees might first complete reading assignments, attend lectures, and watch videos illustrating effective approaches to dealing with customer complaints or defusing an office conflict. Then they might form groups to role-play using these approaches in a variety of typical workplace scenarios. These experiences enhance transfer of training, especially when the trainees' newly learned skills are supported and rewarded by their coworkers and supervisors (Kontoghiorghes, 2004).

Staying Goofy

APPLYING PSYCHOLOGY Training programs for employees who portray cartoon characters at major theme parks emphasize the general principle that the organization's goal is to create a fantasy world for customers. This aspect of training helps the employees understand why it is important to follow the rule about remaining in character at all times. The carefully cultivated fantasy world would be disrupted if children were to see "Mickey Mouse" or "Bugs Bunny" holding his headgear under his arm while smoking a cigarette!

Feedback People learn new skills quicker when they receive *feedback* on their performance (Smither, London, & Reilly, 2005). In organizational training, this feedback usually comes from the trainer or other trainees. It takes the form of positive reinforcement following progress, constructive suggestions following errors or failure, and constant encouragement to continue the effort to learn. For example, after one trainee has participated in a videotaped role-play of a new way to deal with an angry customer or a disgruntled employee, the trainer might play the video for the entire trainee group so that everyone can offer comments, compliments, and suggestions for improvement.

Training in General Principles People tend to learn better and remember more of what they learn when they can put new information into a broader context—in other words, when they get some insight into how the information or skill they are learning fits into a bigger picture (Linou & Kontogiannis, 2004). The Linkages sections in this book are designed specifically to promote this kind of learning. In organizational settings, the "big picture" approach takes the form of *training in general principles,* which teaches not only how to do things in particular ways but also why it is important to do so. When training new customer service agents at a hotel, a bank, or an airline, for example, trainers often include an orientation to the basic characteristics of these businesses, including how competitive they are. Understanding their company's need to survive intense competition will help employees recognize the importance of courtesy training in determining whether a customer remains a customer or goes elsewhere.

Overlearning Practice makes perfect in all kinds of teaching and training, so I/O psychologists emphasize the need for employees to practice using the information and skills learned in a training program until they reach a high level of performance. In fact, many training programs encourage employees to continue practicing until they are not only highly competent but are also able to perform the skill or use the information automatically without having to think much about it. This *overlearning* is seen in many everyday situations, most notably among experienced drivers, who can easily get from one place to another without paying much attention to the mechanics of steering, braking, and turning. Athletes and musicians, too, practice until their skills seem to unfold on their own. In the workplace, overlearning can save time and improve efficiency. For example, members of an experienced medical team can perform surgery using skills and information that, through overlearning, have become second nature to them. They do not have to stop to think about how critical tasks must be done; they simply do them.

Sequencing Is it better to cram organizational training into one or two long, intense sessions over a single weekend or to schedule it in several shorter sessions over a longer period? Obviously, an intense, *massed training* approach is less expensive and less disruptive to employees' work schedules than *distributed training.* However, I/O psychologists know that, as described in the learning chapter, people do not retain as much after massed training as they do after distributed training (Rohrer & Pashier, 2007). Among other problems, massed training can lead to boredom, inattention, and fatigue, all of which interfere with the learning and retention of new material. As most students can appreciate, an employee may remain motivated and interested during a one-hour training session but will probably be exhausted and inattentive by the end of an eight-hour training marathon. With this in mind, organizational training programs are often set up on a distributed schedule whenever possible.

Evaluating Training Programs

Did a training program produce enough benefits to the organization to make it worth the time and money it cost? Should it be repeated? If so, should it be refined in some way? I/O psychologists are prepared to conduct research on these important evaluation questions. As described in the chapter on research in psychology, controlled experiments offer a way to draw reasonably strong cause-and-effect conclusions about the impact of a training program. A representative sample of employees who need training would be selected and then randomly assigned either to receive training or to spend an equivalent amount of time away from their jobs pursuing some alternative activity. The value of the training program could then be measured in terms of the size of the difference in job performance between the trained (experimental) group and the untrained (control) group. However, organizations rarely request experimental research on their training programs. Most of them merely hope that what seemed to be valuable training did, in fact, deliver information and build skills that will be retained by employees and will improve their job performance. Accordingly, evaluation tends to focus on nonexperimental designs using criteria such as employees' reactions to training, what they remember about it, and the changes in behavior that follow it.

Evaluation Criteria The first kind of evaluation criteria, called *training-level criteria,* includes data collected immediately after a training session. Trainees are typically asked to fill out questionnaires about how much they liked the training and how valuable they felt it was. Training sessions that receive low ratings on enjoyment, value, and effectiveness are not likely to be repeated in the same format, especially if the sessions are also low on other criteria.

A second class of criteria, called *trainee learning criteria,* includes information about what trainees actually learned from the training program. These criteria are usually measured by a test, similar to a college final exam, that is designed to determine each trainee's knowledge and skills in the areas covered by the training. In some cases, alternative forms of this test are given to the trainees both before and after training to assess how much improvement has taken place.

Finally, *performance-level criteria* measure the degree to which the knowledge and skills learned in training transferred to the employee's workplace behavior. If employees now know how to do a better job on the assembly line or at the hotel's front desk but do not apply this knowledge to improve their performance, the training program has not been successful. So organizations often evaluate training on the basis of criteria such as number or quality of products produced or frequency of customer complaints. Significant improvements following training may be a result of that training, but because so few organizations conduct controlled experimental evaluations of training, drawing this conclusion is usually risky. The improvement may have had less to do with the training than with some uncontrolled factor, such as a downturn in the economy that motivated employees to work harder in an effort to keep their jobs.

I/O psychologists recommend evaluating training programs on as many criteria as possible because the apparent value of training can depend on which criteria you consider (Sitzmann et al., 2008). A program that looks great on one criterion might be dismal on another. In particular, many programs that get high employee ratings on enjoyment, value, and other training-level criteria fail to show effectiveness in terms of increased productivity, efficiency, or other performance-level criteria (Alvarez, Salas, & Garofano, 2004; May & Kahnweiler, 2000). For example, one training program that was designed to improve employees' interviewing skills received high ratings from the trainees, who showed improved interviewing during training. Unfortunately, these skills did not transfer to real interview situations (Campion & Campion, 1987). ("In Review: Recruiting, Selecting, and Training Employees" summarizes our discussion of these topics.)

IN REVIEW Recruiting, Selecting, and Training Employees

Process	Methods
Recruitment	Perform hiring needs assessment; place ads in newspapers and on Web sites; contact employment agencies; conduct campus interviews; solicit nominations from current employees; accept walk-in applications
Selection	Measure candidates' knowledge, skill, ability, and other personal characteristics using interviews, tests, and assessment centers; conduct validation studies to ensure that these KSAO criteria predict job success
Training	Conduct training needs assessment; design training to promote transfer of training, feedback, understanding of general principles, overlearning, and distributed practice sequencing; evaluate training in terms of employee ratings of the experience and improvement in employee performance

1. **Employees tend to remember more from a training program when it is set up on a ____________ rather than a ____________ schedule.**
2. **Depending on walk-in applications is usually acceptable when hiring ____________ level employees.**
3. **Ensuring that your hiring criteria actually predict employees' job performance requires a ____________.**

Employee Motivation

In the chapter on motivation and emotion, we define *motivation* as the reason people behave as they do. It includes biological, emotional, cognitive, and social factors that influence the direction, intensity, and persistence of behavior (Reeve, 1996; Spector, 2003). These factors are as important in the workplace as they are anywhere else. We can see motivation affecting the *direction* of work-related behavior in people's decisions about whether to work and what kind of job to seek. The effect of motivation on the *intensity* of work can be seen in how often an employee misses work, shows up late, works overtime, or goes beyond the call of duty. Motivation is also reflected in a worker's *persistence* at a task. Some employees give up as soon as difficulties arise, perhaps not bothering to pursue information if it is hard to find. Others keep trying, using every strategy possible until their efforts are successful.

Let's consider three theories that I/O psychologists have used to increase our understanding of employee motivation. One theory focuses on general factors that can affect behavior in the workplace and all other areas of life, too. The others highlight factors that are more specifically associated with motivation in the workplace.

ERG Theory

In the chapter on motivation and emotion, we describe Abraham Maslow's theory in which human behavior is seen as based on a hierarchy of needs or motives (Maslow, 1943, 1970). These motives range from such basic physiological needs as food and water to higher needs, such as those for esteem and self-actualization (see Figure 11.6). Maslow believed that people have to at least partially satisfy needs at the lower levels of the hierarchy before they will be motivated by higher-level goals. As discussed in the motivation and emotion chapter, though, this is not always true. Hunger strikers, for example, ignore their need for food in order to pursue a protest that brings them closer to self-actualization.

To address some of the problems in Maslow's theory, Clayton Alderfer (1969) proposed **existence**, **relatedness**, **growth (ERG) theory**, which places human needs into three rather than five categories: *Existence needs* are things, such as food and water, that are necessary for survival. *Relatedness needs* involve the need for social contact, especially having satisfying interactions with and attachments to others. *Growth needs* are those involving the development and use of a person's capabilities. These three categories of needs form a continuum from the most concrete (existence) to the most abstract (growth), but ERG theory does not suggest that they must be satisfied in a particular order. Instead, the strength of people's needs in each category is seen as rising and falling from time to time and from one situation to the next. If a need in one area is fulfilled or frustrated, a person may be motivated to pursue some other needs. For example, after a relationship breakup frustrates relatedness needs, a person might focus on existence or growth needs by eating more or volunteering to work late. Similarly, losing a job frustrates growth needs, so a laid-off employee might focus on relatedness needs by seeking the social support of friends. Finally, a person obsessed with work-related growth needs might ignore friends until after a big project is completed and it is time to party.

I/O psychologists apply ERG theory in the workplace by helping organizations recognize that employees may not be as motivated to pursue job-related growth needs if other need categories are frustrated or unfulfilled. We will see later, for example, that many organizations now allow flexible working hours in the hope that employees will be more motivated on the job once they can more easily satisfy family-oriented relatedness needs. Organizations also encourage employees—especially those in older age groups—to learn new skills and try out new job roles that help satisfy growth needs (Kanfer, Chen, & Pritchard, 2008).

existence, relatedness, growth (ERG) theory A theory of motivation that focuses on employees' needs at the level of existence, relatedness, and growth.

expectancy theory A theory of workplace motivation in which employees act in accordance with expected results and how much they value those results.

Expectancy Theory

A second approach to employee motivation is similar in many ways to Julian Rotter's expectancy theory (Rotter, 1954, 1982), which is discussed in the personality chapter. It seeks to explain how cognitive processes affect the impact of salary, bonuses, and other rewards on employees' behavior (Vroom, 1964). The main assumption of **expectancy theory** in the workplace is that employees behave in accordance with the results they expect their actions to bring and how much they value those results. For example, workers' motivation to put out extra effort will increase if they expect a bonus for doing so and if they consider the bonus large enough to be worth the effort. Both expectancy and value are a matter of individual perception, though, so it is difficult to use expectancy theory to predict employee motivation by considering outcomes alone. If some workers don't believe that a supervisor will actually provide a bonus for extra work or if certain individuals are not strongly influenced by money, the prospect of a bonus may not be equally motivating for all employees.

Workplace tests of expectancy theory provide strong support for it. One review of seventy-seven studies showed that how hard employees work and the quality of their work are strongly related to their expectancies about rewards and to the value they place on those rewards (Van Eerde & Thierry, 1996). In short, people tend to work hard when they believe it will be worth the effort. Part of the task faced by I/O psychologists is to help organizations make employees feel that high performance is worthwhile.

Goal-Setting Theory

A third approach to employee motivation, called **goal-setting theory**, focuses on the idea that behavior at work is affected not only by general needs and expectations but also by workers' intention to achieve specific goals. These goals can be short-term, such as finishing a report by the end of the week, or long-term, such as earning a promotion within the next two years. A basic prediction of goal-setting theory is that employees will be motivated to choose, engage in, and persist at behaviors that take them closer to their goals.

Goal-setting theory has proved quite useful in motivating employees. There is evidence that arranging for employees to spend some time setting specific goals can lead to better job performance (Locke & Latham, 1990). Many organizations today encourage their employees to engage in goal-setting activities, but I/O psychologists remind managers that some goals are more useful than others. As described in the motivation and emotion chapter, the most motivating goals are those that are chosen, or at least accepted, by the employees; difficult enough to be challenging but not so difficult as to be impossible; and specific enough (e.g., "increasing sales by 10 percent") to allow employees to keep track of their progress and know when they have succeeded (Latham, 2004; Lord et al., 2010). These characteristics apply not only to individual goals but to group goals as well (Aarts, Dijksterhuis, & Dik, 2008; Wegge & Haslam, 2005).

Job Satisfaction

Success in achieving workplace goals is one of many factors that can affect **job satisfaction**, the degree to which people like or dislike their jobs. Like other attitudes described in the chapter on social cognition, job satisfaction is made up of cognitive, emotional, and behavioral components (Schleicher, Watt, & Greguras, 2004). The cognitive component of job satisfaction includes *beliefs* about the job, such as "this job is too demanding" or "this job always presents new challenges." The emotional component includes positive or negative *feelings* about the job, such as boredom, excitement, anxiety, or pride. Finally, the behavioral component of job satisfaction is seen in how people *act* in relation to their work, perhaps showing up early and staying late or maybe taking every opportunity to avoid work by calling in sick.

Measuring Job Satisfaction

To measure job satisfaction accurately, I/O psychologists explore all three of these attitude components. They also assess employees' attitudes about their jobs in general (a *global approach*) and about various aspects of it (a *facet approach;* see Table 19.4).

goal-setting theory A theory of workplace motivation focused on the idea that employees' behavior is shaped by their intention to achieve specific goals.

job satisfaction The degree to which people like or dislike their jobs.

TABLE 19.4 Facets of Job Satisfaction

TRY THIS Here are the results of a Gallup poll in which workers in the United States reported on their attitudes toward eight facets of their jobs. Notice that workers tend to have differing attitudes about different facets. For example, workers can be satisfied with their coworkers and supervisors but not satisfied with their salaries. How do you feel about your own job as "student"? Try listing the aspects of "studenting" that give you the most satisfaction; then take a poll among your student friends to see which aspects of their studentship give them the most satisfaction.

Facet	Satisfaction Rating (%)
Relationships with coworkers	94
Physical safety conditions of work	91
Supervisor	82
Job security	81
Health insurance	73
Salary	70
Promotion opportunities	64
Retirement plan	61

Source: Gallup (1999).

In most cases, job satisfaction is measured using questionnaires. Some questionnaires, such as the Job in General Scale (Ironson et al., 1989), take a global approach. Others, such as the Job Satisfaction Survey (Spector, 1985), are made up of subscales designed to assess attitudes about several job facets, including pay, promotion, benefits, coworkers, and supervision (see Figure 19.2).

Factors Affecting Job Satisfaction

Satisfaction with a job in general or with its various facets can vary widely from one person to the next, even among people doing the same job in the same organization (Bond & Bunce, 2003; Schleicher, Watt, & Greguras, 2004; Staw & Cohen-Charash, 2005). In other words, some employees like jobs or aspects of jobs that other employees hate. I/O psychologists have studied several environmental and personal factors that can influence people's job satisfaction. Among the environmental factors are the requirements of the job, how much it pays, and how it affects workers' lives outside of the workplace. Among the personal factors are workers' gender, age, and ethnicity.

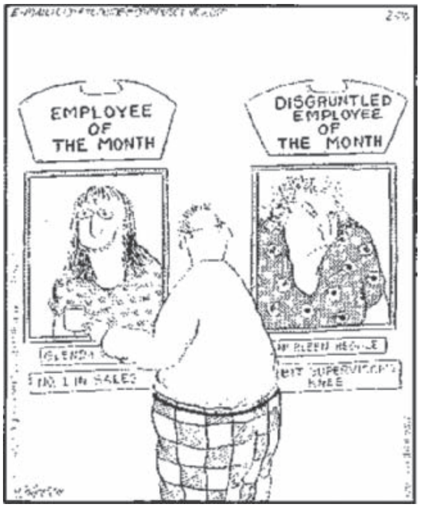
Job Requirements Some jobs, such as those of assembly line workers, involve performing the same relatively simple tasks again and again throughout the workday. Other jobs, such as those in management, are more complex, requiring workers to perform a different set of tasks each day, often in response to unpredictable requests or demands. Is the complexity of a job related to workers' job satisfaction?

FIGURE 19.2

Pay Satisfaction Subscale from the Job Satisfaction Survey

TRY THIS Here are just four items from the pay satisfaction subscale of the Job Satisfaction Survey (Spector, 1985). As its name implies, this subscale focuses on employees' attitudes about the pay they receive in their jobs. Other subscales assess attitudes toward other job facets, such as promotion opportunities, benefits, coworkers, and supervisors. If you have a job, rate it on all these facets, and then compare your ratings with those of a friend or coworker. What facets would you add to make rating forms like this one give a better picture of job satisfaction?

Please circle the one number for each question that comes closest to reflecting your opinion about it.	Disagree very much	Disagree moderately	Disagree slightly	Agree slightly	Agree moderately	Agree very much
1. I feel I am being paid a fair amount for the work I do.	1	2	3	4	5	6
2. Raises are too few and far between.	1	2	3	4	5	6
3. I feel unappreciated by the organization when I think about what they pay me.	1	2	3	4	5	6
4. I feel satisfied with my chances for salary increases.	1	2	3	4	5	6



CLOSE TO HOME © 2004 John McPherson. Reprinted with permission of Universal Uclick. All rights reserved

Surveys of job satisfaction usually find that some employees are more satisfied than others, and these differences can affect how various employees do their jobs.

In general, yes; people tend to be more satisfied with jobs that are more complex (Chung-Yan, 2010; Melamed, Fried, & Froom, 2001). As described in the chapter on motivation and emotion, this higher satisfaction may relate to the fact that more complex jobs tend to be more interesting, more challenging, and more likely to create a sense of responsibility and control in setting and achieving goals (Maynard, Joseph, & Maynard, 2006). However, not everyone responds to complex jobs in the same way (Jex et al., 2002). A complex job may generate dissatisfaction among people who do not have the KSAOs to do it successfully. Even individuals who have the necessary knowledge and skills may be dissatisfied with a complex job if their personality characteristics lead them to prefer simpler, less intellectually demanding work (Loher et al., 1985).

Salary Many workers feel underpaid, but as discussed in the motivation and emotion chapter, higher salaries alone do not necessarily lead to higher levels of job satisfaction (Tang, Tang, & Homaifar., 2006). One study of recent college graduates found a correlation of only +.17 between starting salary and overall job satisfaction (Brasher & Chen, 1999). A main reason for such a low correlation is that a good salary may not compensate for unsatisfactory aspects of a job, such as poor working conditions or lack of respect from supervisors. In fact, knowing that salary and pay raise decisions are made in a fair way can be more important to job satisfaction than the amount of money employees receive (Cloutier & Vilhuber, 2008; DeCremer et al., 2010; Liao & Rupp, 2005). As a result, students working at low-paying jobs may be more satisfied than executives who earn six-figure salaries. The students' satisfaction may come from knowing that everyone doing the same job is getting the same pay, whereas the executives may experience a sense of *relative deprivation,* the perception that others are unfairly receiving more benefits for the same or lesser effort (see the social cognition chapter).

Work-Family Conflict The number of two-career couples and single-parent families is on the increase in the industrialized world (e.g., Demo, Allen, & Fine, 2000; Weinraub, Horvath, & Gringlas, 2002), meaning that more and more people experience conflict between the demands of a job and the demands of family life (Eby et al., 2005; O'Driscoll, Brough, & Kalliath, 2006). One common example is the conflict that occurs when the need to care for a sick child or attend a school play interferes with a parent's work responsibilities. Work-family conflict appears highest among police officers, firefighters, physicians, and others whose jobs require them to be responsible

Minimizing Work-Family Conflict

TRY THIS To help working couples deal with both job demands and family obligations, many organizations have adopted family-friendly programs and policies, including workplace day care services and flexible work schedules (flextime). These programs and policies have been associated with higher levels of job satisfaction and less absenteeism among employees with children (Baltes et al., 1999; Scandura & Lankau, 1997). *Fortune* magazine publishes an annual issue listing the best U.S. companies to work for. Look through this year's issue and the companies' Web sites to see what kinds of family-friendly policies these companies have established.

© Bruce Esbin Photography/The Image Works for others (Dierdorff & Ellington, 2008). Greater work-family conflict is strongly and consistently associated with lower job satisfaction as well as with elevated blood cholesterol levels and lower physical energy (Berkman et al., 2010; Ford, Heinen, & Langkamer, 2007; van Steenbergen & Ellemers, 2009). These relationships appear in both men and women, although the impact of conflict appears to last longer for women (Baltes & Heydens-Gahir, 2003; Grandey, Cordeiro, & Crouter, 2005; Lapierre & Allen, 2006). Partly because of input from I/O psychologists, many organizations are dealing with this source of job dissatisfaction by establishing *family-friendly work policies* that help employees balance work and family responsibilities. One of these policies, called *flextime,* allows parents to work an eight-hour day but frees them from the standard 9:00 A.M.–to–5:00 P.M. schedule. One parent can come to work at, say, 9:30 A.M. after taking the children to school and then stay on the job until, say, 5:30 P.M. to complete an eight-hour day. The other parent can start work at, say, 7:30 A.M. and then leave early to pick up the children from school.

Gender, Age, and Ethnicity Few, if any, gender differences have been found in overall job satisfaction, even when the men and women being compared were doing quite different jobs (e.g., Greenhaus, Parasuraman, & Wormley, 1990; Moncrief et al., 2000). Job satisfaction is related to age, though, with older workers tending to be more satisfied than younger ones (Brush, Moch, & Pooyan, 1987). However, some studies suggest that the picture is a bit more complicated than that (Andreoli & Lefkowitz, 2009; Hedge, Borman, & Lammlein, 2006). For example, among people who enter the world of work immediately after high school or junior college, job satisfaction may at first be quite high but may soon begin to decline, especially among males. Satisfaction ratings then tend to increase slowly but steadily from about age 30 to retirement. This pattern may occur because young workers with relatively little education may find themselves in jobs that are not only poorly paid but also offer few of the features associated with job satisfaction, such as complexity, control over time, and freedom to select goals and tasks (White & Spector, 1987).

Some studies of workers in the United States have found slightly higher job satisfaction among whites than among nonwhites (e.g., Jones & Schaubroeck, 2004; Tuch & Martin, 1991), but others have found no differences (e.g., Brush, Moch, & Pooyan, 1987). In fact, when comparisons are made across groups doing the same jobs, ethnicity does not appear to be a major factor in job satisfaction.

THINKING **CRITICALLY**

Is Job Satisfaction Genetic?

In the chapter on motivation and emotion, we describe evidence that people's overall level of happiness, or *well-being,* may be determined partly by genetics. Could genetic influences also be operating in the workplace in relation to job satisfaction?

What am I being asked to believe or accept?

Richard Arvey and his colleagues (1989) have suggested that differences in job satisfaction reflect genetic predispositions toward liking or not liking a job.

What evidence is available to support the assertion?

As described in the chapters on human development and personality, people's temperament and personality are influenced by genetics. Research in I/O psychology shows that these genetically influenced personality characteristics are related to people's job satisfaction. In one study, for example, hostility and other personality traits that were measured in adolescence were found to be significantly related to job satisfaction up to fifty years later (Staw, Bell, & Clausen, 1986). These data suggest that job satisfaction is at least indirectly shaped by inherited predispositions.

However, Arvey and his colleagues conducted what may be the only study to directly investigate the role of genetics in job satisfaction. They selected a sample of thirty-four pairs of genetically identical twins who had been separated and raised in different environments. They then arranged for these people to complete job satisfaction questionnaires. The questionnaire responses showed a strong positive correlation between the twins' job satisfaction; if one twin was satisfied, the other one tended to be satisfied too. If one was dissatisfied, the other twin tended to be dissatisfied as well. The researchers suggested that because the members of each twin pair had been raised in different environments, genetic factors were at least partly responsible for the observed similarity in job satisfaction ratings.

Are there alternative ways of interpreting the evidence?

These results suggest a strong genetic influence, but they could have been affected by factors other than a genetic predisposition to be satisfied or dissatisfied with a job. For example, although the twins grew up in different home environments, their work environments may have been quite similar. If so, these similar work environments may have produced similar satisfaction ratings. Why would separated twins have similar kinds of working environments? For one thing, the innate abilities, interests, behavioral tendencies, or appearance that identical twins share could have led them into similar kinds of jobs. Some pairs may have selected jobs that tend to be satisfying, whereas other pairs entered jobs that tend to be less satisfying. A pair of bright, athletic, or musically talented twins may have found it possible to have complex, interesting, and challenging jobs and to enjoy a high level of satisfaction. A less fortunate set of twins, having been unable to qualify for the kind of job they might want, may have settled for more routine work that leaves them feeling unsatisfied. In other words, it may be that genes don't shape job satisfaction itself but do shape characteristics that influence people's access to satisfying work.

What additional evidence would help evaluate the alternatives?

One way to assess the impact of job characteristics on the high correlation in twins' job satisfaction ratings is to look at the nature of the twins' jobs. When Arvey and his colleagues did this, they found that the twins did tend to hold jobs that were similar in several ways, including overall job complexity and some of the skills required. A more complete assessment of the jobs and job environments would be required, however, to determine the strength of these nongenetic factors in producing positively correlated job satisfaction ratings.

Together Again

The notion that the inherited characteristics shared by identical twins might lead them into similar jobs was dramatically illustrated in the case of Gary Nisbet and Randy Joubert. Separated as babies thirty-five years earlier, these twins were accidentally reunited when Randy was hired as a furniture mover by the same Waldoboro, Maine, company where Gary already worked—as a furniture mover!

What conclusions are most reasonable?

Research in I/O psychology suggests that individual differences in job satisfaction are probably related to workers' characteristics, some of which are influenced by genetics. However, the precise mechanisms through which genetics might affect job satisfaction are not yet clear (Ilies & Judge, 2003). It is most likely that job satisfaction, like so many other aspects of behavior and mental processes, is shaped by both genetic and environmental influences. There is no single reason why people differ in terms of job satisfaction. How satisfied we are with our work can be predicted to some extent by job characteristics and to some extent by personal characteristics (Gerhart, 2005), but the outcome in a given case is ultimately a matter of who does what job in what organization.

Consequences of Job Satisfaction

Organizations spend a lot of time, money, and effort trying to maintain a reasonable level of job satisfaction among their employees. They do so, if for no other reason, because job satisfaction is linked to a variety of positive consequences for individuals, their coworkers, and their organizations. Dissatisfaction with a job can lead to numerous negative consequences.

Job Performance Research shows that people who are satisfied with their jobs tend to be more motivated, to work harder, and to perform better than employees who are dissatisfied (e.g., Fisher, 2003; Judge et al., 2001; Whitman, van Rooy, & Viswesvaran, 2010). The positive correlation between job satisfaction and performance makes sense, and although a correlation cannot by itself confirm that satisfaction is behind good performance, it is certainly consistent with that conclusion. In fact, one meta-analysis supports the view that job satisfaction and commitment to the organization shape performance rather than the other way around (Harrison, Newman, & Roth, 2006).

Organizational Citizenship Behavior Job satisfaction is also associated with **organizational citizenship behavior (OCB)**, a willingness to go beyond formal job requirements in order to help coworkers or the organization as a whole (Ilies, Scott, & Judge, 2006; Organ, Podsakoff, & MacKenzie, 2006). OCB tends to occur in return for fair treatment employees have received from others or in an effort to support a group to which employees feel connected (Dalal et al., 2009; Kamdar, McAllister, & Turban, 2006; Nishii, Lepak & Schneider, 2008). As in the case of job performance, though, it is difficult to determine whether job satisfaction increases OCB or whether engaging in OCB increases job satisfaction. Further, organizational citizenship behavior might reflect factors other than job satisfaction. One such factor is personality; OCB is particularly likely among people who are high on agreeableness and conscientiousness (Ilies et al., 2009). Other cases of OCB may occur as part of a strategy designed to attain a pay raise, promotion, or other personal goal. In one study, for example, employees who believed it would help their promotion chances engaged in high levels of OCB before being promoted and then reduced their OCB afterward (Hui, Lam, & Law, 2000). Another study found that teachers on temporary contracts felt less secure about their jobs and also engaged in more organizational citizenship behaviors than teachers who held permanent positions (Feather & Rauter, 2004).

Turnover Every organization must deal with a certain amount of *turnover,* or loss of employees. Some turnover is involuntary, as in cases of disability or dismissal, but much of it is voluntary (Harman et al., 2007). Some employees simply quit, and they tend to be employees whose job satisfaction is low (e.g., Griffeth, Hom, & Gaertner, 2000). However, in order to avoid unemployment, few dissatisfied workers quit until and unless they have found another job (Kammeyer-Mueller et al., 2005). So job dissatisfaction is related more strongly to turnover when people are able to find other jobs (Trevor, 2001). When alternative employment is unavailable, even dissatisfied workers tend to stay put.

organizational citizenship behavior (OCB) A willingness to go beyond formal job requirements in order to help coworkers or the organization as a whole.

Efforts to reduce turnover include establishing supportive relationships between new employees, called *protégés*, and more experienced employees, known as *mentors*. Such mentoring programs can be effective, especially when they involve structured rather than informal meetings and when care is taken to match protégés with mentors who are most likely to help them (Allen, Eby, & Lentz, 2006; Ortiz-Walters & Gilson, 2005; Payne & Huffman, 2005).

Absenteeism You might expect that absenteeism, like voluntary turnover, would be strongly related to job satisfaction. However, the correlation between job satisfaction and attendance is surprisingly weak. True, there is a tendency for dissatisfied employees to be absent more frequently than those who are satisfied. But other factors, including personal or family illness, work-family conflicts, and the financial consequences of missing work are far more important in determining who shows up and who doesn't (Dalton & Mesch, 1991; Erickson, Nichols, & Ritter, 2000).

Aggression and Counterproductive Work Behavior Job dissatisfaction is one cause of workplace aggression, as well as of theft and other forms of *counterproductive work behavior* (*CWB*). Assaults or murders involving coworkers or supervisors are rare (Barling, Dupré, & Kelloway, 2009; LeBlanc, Dupré, & Barling, 2006), but theft, computer hacking, and other forms of CWB by employees and former employees are commonplace. Employee theft in the United States alone costs organizations billions of dollars each year (Gatewood & Feild, 2001). In fact, employees steal more from their employers than shoplifters steal from retailers (Hollinger et al., 1996). The direct and indirect costs of other forms of CWB, such as sabotage, working slowly, or doing jobs incorrectly, are staggering. But the true cost of CWB can be hard to determine because so much of it goes unnoticed (Bennett & Robinson, 2000).

LINKAGES How do stressors affect job performance? (a link to Health, Stress, and Coping, p. 536)

As illustrated in Figure 19.3, it is often stress in the workplace that leads to job dissatisfaction and negative emotions such as anger and anxiety (Rodell & Judge, 2009; Spector, Fox, & Domalgaski, 2006). These emotions can in turn result in CWB, especially among employees who feel that they have been treated unfairly or have little or no control over workplace stressors (Aquino, Tripp, & Bies, 2006; Fox, Spector, & Miles, 2001; Greenberg, 2002; Penney & Spector, 2005). Why does lack of control matter? As described in the chapter on health, stress, and coping, when people feel that they have control over the work situation, they are more likely to perceive stressors as challenges to be overcome and to try constructive means of meeting those challenges. Suppose that a supervisor suddenly assigns a difficult task to an employee who must complete it by the next day or face serious consequences. If the employee feels sufficiently in control of the situation to complete the task on time, this stressful assignment is likely to be perceived as a challenge to be mastered. If the employee doesn't have that sense of control and believes it is impossible to meet the deadline, this assignment will probably lead to dissatisfaction and negative emotions such as angry resentment. This person is at elevated risk for engaging in CWB directed at the supervisor, the organization, or other employees.

FIGURE 19.3

Job Satisfaction and Counterproductive Work Behavior

Workplace stressors can lead to job dissatisfaction, which leads to negative emotions and counterproductive work behavior, especially among employees who feel mistreated and unable to control stressors.

LINKAGES What causes workplace aggression? (a link to Social Influence, p. 743)

Aggression in the Workplace

In the chapter on social influence, we describe a number of biological, psychological, and environmental factors that appear responsible for triggering human aggression and violence. These factors operate in the workplace, too, though incidents of aggression between or against workers differ in some ways from violence outside the workplace (Hershcovis et al., 2007).

For example, whereas nearly half of murder victims in the United States know their assailants (Cassell & Bernstein, 2007), about 85 percent of workplace homicides are committed against employees by strangers (LeBlanc & Barling, 2004). In other words, despite well-publicized cases of disgruntled employees killing coworkers or supervisors, employees actually commit only about 15 percent of workplace homicides and less than10 percent of workplace assaults (LeBlanc & Barling, 2004). Convenience store clerks, taxi drivers, and other employees who deal directly with the public, handle money, and work alone at night are at particular risk to be victims of workplace aggression (LeBlanc, Dupré, & Barling, 2006). Most aggression against these people is *instrumental aggression,* meaning that the aggressor's intent is not necessarily to injure but to attain a goal such as getting money or other valuables (Merchant & Lundell, 2001). Though the perpetrator often uses a weapon to intimidate the employee, these aggressive incidents do not usually result in physical injury.

Most cases of injury in the workplace occur in the course of aggressive assaults by patients or customers on doctors, nurses, and other health workers, sales clerks, and food servers (Büssing & Höge, 2004; LeBlanc & Barling, 2004). Often these injuries occur under stressful circumstances—such as during emergency room treatment—in which pain, anger, fatigue, and frustration lead to an impulsive, emotional, aggressive outburst. In contrast to instrumental aggression, the perpetrator's intent in these cases is to injure the victim.

When aggression does occur between or among employees, the assault is usually verbal, not physical, and the result is usually resentment and bruised feelings, not bruised bodies (Barling, Dupré, & Kelloway, 2009; Grubb et al., 2005). Like road rage incidents, employee-to-employee aggression is often the by-product of an impulsive, emotional outburst under time pressure or other stressful conditions, including workplace injustices or abusive supervision (Berry, Ones, & Sackett, 2007; Inness, Barling, & Turner, 2005). Sometimes, though, this form of aggression may reflect an attempt by one employee to control others through bullying or intimidation (Grubb et al., 2005).

Occupational Health Psychology

In the chapter on health, stress, and coping, we defined *health psychology* as a field devoted to understanding psychological factors in how people stay healthy, why they become ill, and how they respond when they do get ill (S. E. Taylor, 2002). **Occupational health psychology** is concerned with psychological factors that affect the health, safety, and well-being of employees in the workplace. I/O psychologists promote the goals of occupational health psychology by consulting with organizations about ways to reduce threats to employees posed by undue stress, accidents, and hazards. Their success in this enterprise is reflected in the fact that today, most workplaces are safer and healthier than employees' own homes (National Safety Council, 2004).

Physical Conditions Affecting Health

occupational health psychology A field concerned with psychological factors that affect the health, safety, and well-being of employees.

Many physical conditions in the workplace have the potential to cause illness and injury (Lund et al., 2006). Accordingly, in the United States, the government's Occupational Safety and Health Administration (OSHA) establishes regulations designed to minimize employees' exposure to hazards arising from infectious agents, toxic chemicals, dangerous machinery, and the like. For example, to guard against the spread of AIDS,

Doing It Over and Over

TRY THIS Performing the same movements on the job hour after hour and day after day can lead to *repetitive strain injuries*. This employee's keyboard movements resulted in a painful and potentially disabling condition called *carpal tunnel syndrome*. Wearing a wrist brace can reduce the pain somewhat, but I/O and engineering psychologists know that improved wrist support for keyboard users can help prevent the problem in the first place. To appreciate the impact of psychologists' consultation efforts, browse some online computer equipment catalogs, such as geeks.com or tigerdirect.com, and calculate the percentage of keyboards, mice, and other devices that have been designed to minimize the possibility of repetitive strain injuries.

© Mark Richards/PhotoEdit

U.S. doctors, dentists, nurses, and other health care workers have been asked to follow a set of safety procedures called *universal precautions*. These precautions include wearing disposable gloves when drawing blood, giving injections, or performing dental procedures and also discarding needles and other sharp objects into special sealed containers.

These procedures can be effective in reducing the spread of disease, but because of heavy workloads and lack of encouragement from supervisors, health care workers do not always follow them (McDiarmid & Condon, 2005). I/O psychologists play a role in this aspect of occupational health psychology by promoting organizational support for following proper safety procedures and by designing safety training that employees will actually apply in the workplace (Smith-Crowe, Burke, & Landis, 2003). They also help protect employees' health by creating reminders to use caution on the job and by consulting with organizations to minimize stressors that can lead to illness or injury.

One of these stressors comes in the form of jobs that require performing certain movements in the same way over long periods of time, such as turning a screwdriver or making cut after cut in pieces of plastic. Eventually, these movements can create *repetitive strain injuries* in which joints become inflamed, sometimes causing permanent damage. The most familiar of these injuries is *carpal tunnel syndrome*, a condition of the wrist that produces pain, numbness, and weakness in the fingers. Although typically associated with using a computer keyboard or mouse, carpal tunnel syndrome can be caused by many other activities involving the fingers and wrists. Psychologists have been involved in two approaches to preventing repetitive strain injuries. First, as described in the introductory chapter, those working in *engineering psychology* (also called *human factors*) consult with industrial designers to develop equipment and tools that are less physically stressful to use. One result of their efforts is the wrist-rest pads that are commonly seen in front of computer keyboards used by people who perform typing tasks for many hours each day. These pads provide support and also keep the typists' wrists from twisting. Second, I/O psychologists are working with organizations to ensure that employees whose jobs require repetitive actions be allowed to take breaks that are long enough and frequent enough to rest the body parts at risk for strain injuries. These psychologists are also working with employees themselves to make sure that they follow the recommended break schedule.

Work Schedules, Health, and Safety

The flextime arrangements mentioned earlier that allow some employees to adjust their working hours are part of a more general trend away from the traditional 9:00 A.M.–to–5:00 P.M. workday. As many organizations expand their hours of service—some of them to twenty-four hours a day, seven days a week—more and more employees are on the job during what would once have been considered "odd hours." They may work at night or on weekends, and they follow shift patterns once associated mainly with hospital, law enforcement, and factory employees. Others are working more than eight hours a day but fewer than five days a week, and in the face of staffing cutbacks, still others may be working more than forty hours a week. Whether undertaken by choice or by assignment, these nontraditional work schedules can cause stress and fatigue that can adversely affect employees' health (Burch et al., 2009).

Rotating Shift Work These negative effects can be especially great among employees who change work shifts from week to week—rotating from evenings to days to nights, for example (Demerouti et al., 2004). As described in the chapter on consciousness, these shift changes disrupt employees' *circadian rhythms* of eating, sleeping, and wakefulness, resulting in a number of unpleasant mental and physical symptoms. A major problem with working night shifts, for example, is fatigue, irritability, and reduced cognitive sharpness resulting from difficulty in getting to sleep or staying asleep during the day (Daus, Sanders, & Campbell, 1998). Some shift workers also experience upset stomachs and other symptoms of digestive distress (Rouch et al., 2005). These problems may be far less troubling for workers whose night shift assignments last long enough that they can get used to their "backward" schedule (Barton & Folkard, 1991), but rotating shift work can also be disruptive to employees' social relationships and may lead to work-family conflicts (Barnes-Farrell et al., 2008). Absenteeism, too, may increase, especially among younger workers who are new to shift work, and there is some evidence that burnout and earlier retirement are more common among workers on rotating shifts than among those on fixed schedules (Shen & Dicker, 2008).

Long Shifts and Long Weeks Many organizations today are establishing longer-than-normal work shifts. For example, some have set up ten-hour shifts that allow employees to work forty hours in four days, thus giving them an extra day off. Others

Staying Sharp

APPLYING PSYCHOLOGY I/O psychologists' research on the negative impact of extended work shifts has led to organizational and U.S. government rules requiring rest breaks at fixed intervals for commercial airline pilots, long-haul bus and truck drivers, and others whose jobs require constant attention to complex tasks and systems. These rules also limit the total number of hours these employees can work in any twenty-four-hour period.

have replaced three eight-hour work shifts with a more efficient system of two twelve-hour shifts that allow workers even more time off.

Many employees like such arrangements; longer shifts can lead to greater job satisfaction and better job performance (Baltes et al., 1999). However, extended workdays may cause health and performance problems for some workers in some jobs (Lamberg, 2004; Loudoun, 2008). This possibility is suggested by research on drivers of intercity buses. Those who drove longer routes that required being on the road for up to fourteen hours a day with few rest breaks tended to use stimulants to stay alert, to drink alcohol to counteract the stimulants after arrival, and to experience sleep disturbances, various physical symptoms, anxiety, and fatigue. They were also more likely than shorter-shift drivers to be involved in accidents (Raggatt, 1991).

There are also dangers in requiring employees to work more than forty-eight hours per week, especially when they would prefer not to do so. These involuntary workweek extensions have been associated with a number of employee health problems, particularly heart disease (Sparks et al., 1997). Accordingly, nations of the European Union have adopted regulations setting workweeks at a maximum of forty-eight hours. So far, there are no such government regulations in the United States.

Stress, Accidents, and Safety

Although most accidents occur away from the job, workplace safety is still a major focus of organizations and of I/O psychologists. In just one recent year, 5,734 workers were killed and 4.2 million others were injured on the job in the United States alone (U.S. Bureau of Labor Statistics, 2007). Motor vehicle accidents account for nearly half of workplace fatalities. Falls and equipment accidents account for about another one-third of these deaths.

Longer-than-normal work shifts and extended workweeks are among many sources of occupational stress that contribute to the fatigue, inattention, cognitive impairment, sleepiness, and other problems that elevate the risk of workplace accidents. I/O psychologists have identified numerous other individual and organizational factors that contribute to stress-related accidents, including lack of clear instructions, heavy workloads, concern about job security, sexual harassment or ethnic discrimination, burnout, and workplace bullying (Berdahl & Moore, 2006; Hoel, Faragher, & Cooper, 2004; Schabracq, 2003; Schneider, Hitlan, & Radhakrishnan, 2000; Sparks, Faragher, & Cooper, 2001). Accidents are also more likely when the *climate of safety* in the workplace is poor, meaning that there is a lack of safety training, too little supervisory emphasis on following safety rules, and a tendency for workers to ignore those rules (Beus, et al., 2010; Clarke, 2006; Griffin & Neal, 2000). Accidents are least common in organizations that provide adequate safety training for employees, conduct thorough and frequent safety inspections, and ensure that supervisors consistently communicate the need for safety (Christian et al., 2009; Hansez & Chmeil, 2010; Newman, Griffin, & Mason, 2008).

Work Groups and Work Teams

A great deal of workplace activity is accomplished by groups of individuals working together. Industrial and organizational psychologists have been at the forefront of efforts to help organizations maximize the effectiveness and efficiency of work groups and work teams. A **work group** is defined as two or more people who interact as they perform the same or different tasks. The four servers waiting on customers during the dinner shift at a restaurant would be an example of a work group. A **work team** is a special kind of work group in which the members' activities are coordinated and interdependent, each member has a specialized role, and members are working toward a common goal (West, Borrill, & Unsworth, 1998). The entire staff on duty during the restaurant's dinner shift would be considered a work team. All members of the team are working on the same task with the same goal in mind—namely, to serve that evening's customers as quickly

work group Two or more people who interact as they perform workplace tasks.

work team A work group in which the members' specialized activities are coordinated and interdependent as they work toward a common goal.

Medical Teamwork

The doctors, nurses, and technicians who join forces to perform surgery are a perfect example of a work team. Everyone on the surgical team is devoted to the same goal of completing a successful operation, but each performs a somewhat different task in a coordinated manner under the direction of the surgeon, who acts as the team leader.

© Lester Lefkowitz/Corbis

and efficiently as possible. Further, each team member has a specialized role: Greeters seat customers, servers take orders and deliver the food, cooks prepare the food, and managers monitor progress, direct employees, and fill in at various tasks as needed. Whether it involves food service, brain surgery, automobile repair, or other workplace activities, an effective work team performs "like a well-oiled machine."

Promoting this kind of efficiency, especially in work groups and work teams whose members come from diverse cultural and ethnic backgrounds, is one of the most important challenges faced by I/O psychologists today (Kozlowski & Ilgen, 2006; Silverthorne, 2005). In addressing this challenge, they have distinguished between the "surface diversity" seen in racial and gender differences and the "deep diversity" of work group members' differing attitudes and values (Harrison et al., 2002). So they seek to improve the performance of diverse work groups partly by helping them overcome any problems relating to surface diversity but also by encouraging them to capitalize on deep diversity through the identification and exploitation of members' differing and perhaps even unique perspectives, expertise, and knowledge (van Emmerik & Brenninkmeijer, 2009).

Autonomous Work Groups

In most organizations, work groups and work teams operate in a traditional way, meaning that as in the case of a restaurant or grocery store, all workers report to a manager who directs and supervises their activities. However, a growing number of organizations today are establishing **autonomous work groups (AWGs)** that manage themselves and do not report to anyone for routine daily supervision. Instead, once AWGs are given a work assignment, it is up to them to determine how best to accomplish their goal and then to work together to achieve it. The classic example of AWGs can be seen in the manufacturing sector. Automobiles and other consumer products were once built on long assembly lines by large numbers of workers who each performed only one small part of the process before passing the product on to another worker who performed the next step. In autonomous work groups, however, each member rotates among jobs such that everyone performs every aspect of assembly from time to time. The group members also design and order their own tools, conduct their own product inspections to ensure quality and performance, and even participate in hiring and firing decisions. Many brands of automobiles and other large pieces of equipment are

autonomous work groups (AWGs) Self-managed employee groups that do not report to anyone for routine daily supervision.

now assembled in AWG factories that feature a series of workstations where perhaps a half-dozen employees assemble the entire product or a substantial portion of it.

Autonomous work groups have benefits for employees and for organizations. In one comparison study, employees in AWG factories reported higher levels of job satisfaction than employees of traditional factories (Cordery, Mueller, & Smith, 1991). Further, the productivity of AWGs has been shown to be at least as good as traditional arrangements despite the fact that AWGs cost less in the long run because organizations don't need as many supervisors (Banker et al., 1996; Glassop, 2002; Hoegl & Parboteeah, 2006; Stewart, 2006). AWGs may be particularly effective when they are created in organizations that had previously suffered from an inefficient and unsatisfying work climate (Morgeson et al., 2006).

Group Leadership

Workplace groups almost always have leaders. Even in autonomous work groups, leaders usually emerge (Foti & Hauenstein, 2007; Zaccaro, Heinen, & Shuffler, 2009), although the leadership roles may sometimes be shared by more than one person (Uhl-Bien, Marion, & McKelvey, 2007). And AWGs are themselves embedded in organizations that operate through a leadership hierarchy (Kaiser, Hogan, & Craig, 2008). At each level, designated leaders direct or supervise the activities of others, set group and organizationwide objectives, decide how individual employees can best contribute to those objectives, and make sure employees perform the tasks assigned to them. Let's consider some of the characteristics of good leaders, how good leaders behave, and how they relate to various members of their work groups and work teams.

What Makes a Good Leader? One way to study leadership is to look at lots of leaders to see if particular kinds of knowledge, skill, ability, or other personal characteristics are associated with those who are effective and those who are ineffective. Much of what social and I/O psychologists have learned about the KSAOs of effective leaders comes from research on managers (e.g., Peterson et al., 2003; Zaccaro, 2007). That research suggests that some characteristics are regarded by almost everyone as necessary for good leadership. For example, a large study of leadership effectiveness in sixty-two countries found that being intelligent, trustworthy, and team-oriented were universally rated as important traits of good leaders (House et al., 1999). These results are supported by other studies showing that intelligence is consistently important for competent managerial performance (Chemers, Watson, & May, 2000; Judge, Colbert, & Ilies, 2004). In other words, smarter leaders tend to be better leaders. Good leaders also tend to score high on agreeableness, emotional stability, extraversion, and conscientiousness (Silverthorne, 2001). The value of other leadership traits can depend on social, cultural, and situational factors (Felfe & Goihl, 2002). For instance, a willingness to take risks tends to be seen as a positive leadership trait in some countries and as a negative trait in other countries (House et al., 1999).

How Do Good Leaders Behave? Another way to study leadership is to explore the things that effective and ineffective leaders do. The foundation for this research was provided by the Ohio State leadership studies, which began in 1945. The first step in this extensive program was to collect eighteen hundred "critical incidents" of effective and ineffective leader behavior. An incident of "effective" leadership might be to suggest that a troubled employee transfer to a less demanding job. An incident of "ineffective" leadership might be to shout at an employee who questioned the leader's decision. These and other studies have revealed that specific kinds of leader behaviors can have profound effects on group members and organizations. For example, one study found that army platoons led by active and involved leaders were especially effective under combat conditions (Bass et al., 2003).

The Ohio State researchers identified two dimensions on which leaders typically vary. The first, called *consideration,* is the degree to which a leader shows concern for the welfare of employees, including friendly and supportive behavior that makes the workplace more pleasant. The second dimension, called *initiating structure,* is the degree to which a leader coordinates employee efforts by assigning tasks and clarifying expectations so that group members know what is required of them to perform well.

Relationship-motivated leaders (described in the social influence chapter) tend to be high on the consideration dimension, while task-motivated leaders tend to be high on the initiating-structure dimension. Where managers fall on each of these dimensions of leadership style can have important effects on employees (Eagly, Johannesen-Schmidt, & van Engen, 2003; Judge, Piccolo, & Ilies, 2004; Keller, 2006; Zaccaro, 2007). In one study, workers in a truck manufacturing plant were asked to rate their immediate supervisors on the consideration and initiating-structure dimensions (Fleishman & Harris, 1962). These ratings were then related to the number of formal complaints these employees filed against their supervisors and the rate at which they quit their jobs (voluntary turnover). Grievances and turnover were much higher among employees whose supervisors had been rated low on consideration than among those whose supervisors had been rated high on consideration. More grievances were also filed by employees whose supervisors were higher on initiating structure, but there is more to that part of the story. The highest rates of grievance and turnover occurred among employees whose supervisors who were not only high on initiating structure but also low on consideration. As long as supervisors were high on consideration, they could be high on initiating structure without creating a lot of grievances and turnover. In other words, it is possible for a leader to be firm but fair, thus promoting maximum performance with a minimum of complaints and employee losses.

Leader-Member Interactions Are leadership styles like the relatively stable traits described in the personality chapter? Do they create consistent leadership behaviors toward all group members in all situations? Some leaders might fit this description, but **leader-member exchange (LMX) theory** suggests that most leaders tend to adopt different styles with two different kinds of subordinates (Bhal et al., 2009; Dansereau, Graen, & Haga, 1975). Leaders tend to offer the most consideration and best treatment to subordinates who make up the employee *ingroup.* These individuals tend to be the best performers and are regarded by the leader as competent, trustworthy, loyal, and dependable (Bauer & Green, 1996). As such, ingroup members' opinions and requests tend to carry more weight with the leader than those of *outgroup* employees, whom the leader regards as less competent, less reliable, and potentially expendable. Ingroup members may also benefit from having "inside" information from the leader, more helpful mentoring, and perhaps even inflated performance evaluations (Duarte, Goodson, & Klich, 1993; Scandura & Schriesheim, 1994). Leaders give outgroup employees less opportunity to influence decisions and tend to supervise them by giving high structure and low consideration (Dansereau, Graen, & Haga, 1975). More than eighty stud ies of leader-member interaction patterns support the existence of employee ingroups and outgroups and the tendency for ingroup members to experience more job satisfaction and less occupational stress and to more often engage in organizational citizenship behaviors (Gerstner & Day, 1997; Ilies, Nahrgang, & Morgeson, 2007; Schyns, 2006).

Traditional leadership models are based on situations in which there is face-to-face interaction among team members and leaders. Do these models apply equally well to "virtual teams" whose members communicate electronically via e-mail or videoconferencing from different parts of the country or different parts of the world (Zigurs, 2003)? Industrial and organizational psychologists are investigating this question (e.g., Xiao et al., 2008), and early results suggests that LMX theory may not fully capture the interactions of leaders and subordinates in virtual team situations (Avolio, Walumbwa, & Weber, 2009; Uhl-Bien, Marion, & McKelvey, 2007). Future research on e-leadership will undoubtedly expand our understanding of leadership as it operates in today's increasingly technology-driven workplaces and among increasingly diverse workgroups (Eagly & Chin, 2010).

leader-member exchange (LMX) theory A theory suggesting that leaders tend to supervise ingroup and outgroup employees in different ways.

FOCUS ON RESEARCH METHODS

A Charismatic Leader

Former British prime minister Margaret Thatcher is considered by many to exemplify the kind of leader whose charisma inspires followers to accomplish what they might not otherwise have done.

Can People Learn to Be Charismatic Leaders?

Some people's leadership abilities are so effective that they are described as charismatic. A *charismatic leader* is one who inspires followers to embrace a vision of success and to make extraordinary efforts to achieve things they would not have done on their own (Bass & Riggio, 2006; Erez et al., 2008). Charismatic leaders like Martin Luther King Jr. and Winston Churchill captured the imaginations of their followers. King led the fight for civil rights in the 1960s, inspiring countless thousands of followers to overcome entrenched opposition and personal danger to achieve the long-sought goal of equality under the law for African Americans. Prime Minister Churchill rallied the British people to resist and overcome the effects of Nazi air attacks during the darkest days of 1940 and throughout World War II. It has long been assumed that charismatic leadership is a by-product of a charismatic personality, not something that one can learn.

What was the researcher's question?

I/O psychologists wonder whether that assumption is correct. Might it be possible to train leaders to be charismatic, and if so, how would such training affect the job satisfaction and performance of those leaders' employees? Julian Barling, Tom Weber, and E. Kevin Kelloway (1996) addressed these questions by designing and evaluating a charisma-building training program for corporate managers.

How did the researchers answer the question?

Their study was conducted in twenty branches of a large Canadian banking corporation. The managers of these branches were randomly assigned to a charisma training group or a control group that received no training. Two weeks before training began and again five months after it was completed, the people working for each manager filled out a questionnaire on which they rated their manager's charisma. They also reported on their own level of job satisfaction. In addition, the financial performance of each branch office was measured before and after training.

Charisma training was delivered in five sessions over a three-month period. At the first session, managers met as a group to spend an entire day learning what makes charismatic leaders charismatic and practicing these behaviors in order to increase their own charisma. In the next four sessions, managers worked individually with one of the researchers, receiving additional training, getting feedback on performance, and setting goals for further progress.

What did the researchers find?

All the results indicated that this training program had a positive impact on managers' charisma. First, branch employees' ratings showed that managers in the training group were now more charismatic. There was a small decline in charisma for those in the control group. Second, those who worked for the charisma-trained managers reported higher levels of job satisfaction after training was over than those who worked for the untrained managers. Finally, the financial performance of the trained managers' branches increased, whereas that of the untrained group decreased somewhat.

What do the results mean?

This charisma training program may not have produced a Martin Luther King Jr. or a Winston Churchill, but its impact supports the notion that charisma can be taught, at least to some extent (Frese, Beimel, & Schoenborn, 2003). The trained managers became more charismatic and more effective than their untrained colleagues, suggesting that charisma involves behavior that can be learned by people with many different personality characteristics.

What do we still need to know?

The findings of this study are encouraging, but we should be cautious in interpreting them. For one thing, the changes seen in the trained managers may have been due to factors other than the training itself. As described in the chapter on research in psychology, improvements following some treatment may be due partly or largely to placebo effects or other factors that create positive expectations among research participants. If the managers expected to be better at their jobs as a result of training and if their subordinates expected them to be better managers, it could have been these expectations, not the training, that caused the behavior changes and increased charisma ratings (Groves, 2005). Even the improved financial performance could have been the result of expectation-driven efforts to do better, efforts that had nothing to do with the training itself. Interpreting the results of this experiment would have been easier if members of the untrained group had participated in some sort of placebo control program that, like the charisma training, would have raised their expectations and those of their employees.

Even if the training program actually was responsible for the improvements seen, it would be important to know if its effects will last beyond the five-month follow-up period. If it does have long-term effects, it would then be important to evaluate the charisma training with leaders in other kinds of organizations and at other levels of leadership. It will take time and a lot of research to explore these matters, but if charisma can indeed be taught, we may someday see candidates for political office lining up to learn it.

LINKAGES

As noted in the introductory chapter, all of psychology's many subfields are related to one another. Our discussion of aggression in the workplace illustrates just one way in which the topic of this chapter, industrial and organizational psychology, is linked to the subfield of social psychology, which is covered in the chapters on social cognition and social influence. The Linkages diagram shows ties to two other subfields as well, and there are many more ties throughout the book. Looking for linkages among subfields will help you see how they all fit together and better appreciate the big picture that is psychology.

Social Influence

SUMMARY

An Overview of Industrial and Organizational Psychology

Industrial and organizational (I/O) *psychology* is the science of behavior and mental processes in the workplace. I/O psychologists not only study the psychology of the workplace but also apply psychological research to enhance the performance of employees and organizations and to improve the health, safety, and well-being of employees. I/O psychology grew out of experimental psychology early in the twentieth century as psychologists began to apply laboratory research to workplace problems.

Assessing People, Jobs, and Job Performance

The development and evaluation of methods for assessing employees, jobs, and job performance is one of the main areas for scientific research in I/O psychology.

Knowledge, Skills, Abilities, and Other Characteristics

The human attributes necessary for doing jobs successfully are referred to collectively as *KSAOs,* which stands for knowledge, skill, ability, and other personal characteristics.

Job Analysis

A *job analysis* is the assessment of jobs and job requirements. It may be job-oriented (describing job tasks), person-oriented (describing the KSAOs necessary to perform job tasks), or personality-oriented (focusing on specific personality traits associated with success). Organizations use job analysis information for many purposes, including to guide employee hiring and training.

Measuring Employee Characteristics

The three main methods used to measure employee characteristics are psychological tests, interviews, and assessment centers. Tests can focus on employees' knowledge, abilities, skills, and other characteristics, such as personality traits. A job applicant interview is designed to determine an applicant's suitability for a job. It can be structured or unstructured, but structured interviews are far more effective in selecting successful employees than unstructured interviews, in which no preplanned questions are asked. An *assessment center* is an extensive set of exercises used to determine if a person is suited for a particular job.

Measuring Job Performance

Most organizations give an annual *job performance* appraisal to all employees. Much like a school report card, these appraisals describe how well a person is doing in various job domains. Performance is measured in relation to general (theoretical) criteria as well as in relation to more specific (actual) criteria.

Methods of Performance Appraisal

Objective measures of performance appraisal rely on counting behaviors or the results of behaviors. These measures are valuable, but they are not appropriate for evaluating performance in jobs that have little or no objectively measurable output. Subjective measures can be used in any job situation, but because they rely on supervisor ratings of performance, they may be distorted by judgment bias or error.

Recruiting and Selecting Employees

Assessment tools are used frequently by I/O psychologists to help hire people who will be best able to succeed in particular jobs.

Recruitment Processes

The first step in effective recruiting is to determine what employees are needed and then to attract applicants to fill those needs, using employment agencies, newspaper and Internet advertising, and campus visits; encouraging nominations from current employees; and accepting walk-in applications.

Selection Processes

The I/O psychology approach to hiring is to use scientific principles to match the needs of the job to the KSAOs of applicants. Establishing the KSAO requirements of a job helps determine which employee assessment tools will be most appropriate, and *validation* studies may be used to confirm that particular scores on the chosen assessments actually predict success on the job.

Legal Issues in Recruitment and Selection

Many industrialized countries have established laws and regulations barring discrimination in hiring, firing, or promotion based on ethnicity, age, gender, or any other characteristics unrelated to job performance.

Training Employees

I/O psychologists help organizations establish the need for training, design training methods and content, and evaluate the outcome of training.

Assessing Training Needs

Using a training needs assessment, organizations determine what training employees need to perform their jobs safely and well. Training needs assessments can focus on what KSAOs are required for specific jobs, on what training employees say they need, and on the objectives of the organization, such as to improve production and decrease accidents.

Designing Training Programs

The design of training programs is guided by research on the processes through which people acquire new information and skills. These principles, such as generalization, reinforcement, insight, and practice, are translated into employee training that emphasizes transfer of training (applying newly learned skills in the workplace), feedback (providing reinforcement for progress, as well as guidance and encouragement following errors), training in general principles (providing "big picture" information to show the relevance of training), overlearning (practicing new skills to the point of automaticity), and sequencing (distributing training over time to improve learning and retention).

Evaluating Training Programs

A training program can be evaluated in terms of how trainees felt about the training (training-level criteria), what trainees actually learned during training (trainee learning criteria), and the degree to which trainees used what was learned during training in doing their jobs (performance-level criteria).

Employee Motivation

Motivation in the workplace refers to factors that influence the direction, intensity, and persistence of employees' behavior. Three motivational theories have special workplace applications.

ERG Theory

ERG theory divides human needs into existence needs (such as food and water), relatedness needs (e.g., social contact), and growth needs (the development and use of one's capabilities). It suggests that the strength of each type of need affects workers' motivation to do their jobs well.

Expectancy Theory

According to *expectancy theory,* employees work hard if they expect a valued reward to result from their efforts. These expectations and the value placed on particular rewards differ from person to person.

Goal-Setting Theory

Goal-setting theory suggests that workers' motivation stems mainly from their desire to achieve short- and long-term goals. Organizations are advised to help employees set clear, specific goals that are challenging but not impossible.

Job Satisfaction

Job satisfaction is a cluster of attitudes that reflect the degree to which people like their jobs.

Measuring Job Satisfaction

Job satisfaction is usually assessed using questionnaires that ask employees to say how they feel about their job in general (global approach) or about pay, supervision, or other specific job components (facet approach).

Factors Affecting Job Satisfaction

I/O psychologists have studied several environmental and personal factors that can influence people's job satisfaction. Among the environmental factors are the requirements of the job, how much it pays, and how it affects workers' lives outside the workplace. Among the personal factors are workers' gender, age, and ethnicity. For the most part, complex jobs tend to be more satisfying than simple jobs. Salary itself may be a less important factor in job satisfaction than the fairness of the salary system. Excessive work-family conflict can reduce job satisfaction. Because of temperament and experience, some individuals may have a tendency to be more satisfied with their jobs than others.

Consequences of Job Satisfaction

Job satisfaction has been associated with better job performance and with *organizational citizenship behavior,* but it isn't clear if satisfaction is a cause or an effect of these attributes. Job dissatisfaction is clearly at work in causing people to quit their jobs (turnover) but has a smaller effect on absenteeism. Job dissatisfaction can also lead to aggression and counterproductive work behavior (CWB) such as theft or sabotage. CWB is especially likely among dissatisfied employees who work under conditions of high stress and low perceived control.

Occupational Health Psychology

Occupational health psychology is concerned with psychological factors that affect the health, safety, and well-being of employees.

Physical Conditions Affecting Health

A number of physical conditions in the workplace can affect health, including infectious agents, toxic chemicals, dangerous machinery, and stressors such as the need to perform repetitive actions.

Work Schedules, Health, and Safety

Work schedules have implications for health and well-being. Rotating shift work, extended shifts, and longer-than-normal workweeks have been associated with a variety of problems ranging from fatigue and sleeping problems to substance abuse and increased risk of heart disease.

Stress, Accidents, and Safety

Most accidents in the United States occur away from work, but workplace safety is still a major concern. Reducing workplace accidents can be accomplished not only by reducing occupational stressors but also by promoting a climate of safety. Workplace accidents are least frequent in organizations that provide rigorous safety training, conduct frequent safety inspections, and encourage adherence to safety procedures.

Work Groups and Work Teams

A *work group* is a collection of people who interact on the job, whereas a *work team* is a group in which members depend on one another as they work at specialized, coordinated tasks aimed at accomplishing a common goal.

Autonomous Work Groups

Unlike traditional, closely supervised work teams, *autonomous work groups* are assigned tasks and then allowed to manage themselves, solve their problems, and even influence hiring and firing decisions, all of which tends to result in greater job satisfaction among autonomous work group members than among members of traditional teams.

Group Leadership

Leaders direct or supervise the activities of others, set group and organizational objectives, and ensure that employees perform their assigned tasks. Certain characteristics, such as intelligence, tend to be universally seen as a desirable leadership attribute; others, such as a willingness to take risks, may not be seen as ideal in all cultures. Two dimensions of leadership style have been found to exert strong effects on employees' performance and job satisfaction. Consideration, which means showing concern for the welfare of employees, is associated with relationship-motivated leaders, while initiating structure (coordinating employee efforts by assigning tasks) is associated with task-motivated leaders. Leaders who are low on consideration tend to have less satisfied employees and higher turnover rates than those who are high on consideration. Leaders high on initiating structure may also create such problems, unless they are also high on consideration. *Leader-member exchange theory* suggests that leaders adopt different styles toward ingroup and outgroup employees. Charismatic leaders have the ability to influence and inspire employees to accomplish things they would not have done on their own. Charisma tends to promote job satisfaction in employees, and there is some evidence that training programs may help managers enhance organizational effectiveness by becoming more charismatic.

LINKAGES TO FURTHER LEARNING

Now that you have finished reading this chapter, how about exploring some of the topics and information that you found most interesting? Here are some places to start.

Books

Duane Schultz and Sydney Ellen Schultz, *Psychology and Work Today* (Prentice Hall, 2005). A readable introduction to I/O psychology.

Paul E. Spector, *Industrial and Organizational Psychology: Research and Practice* (Wiley, 2003). Another excellent introduction to I/O psychology.

Gavin Mortimer, *Shackleton: The Story of Ernest Shackleton and the Antarctic Explorers* (Viking, 2002). A famous example of teamwork and matching people to jobs.

Barbara Ehrenreich, *Nickel and Dimed: On (Not) Getting By in America* (Henry Holt, 2001). About the lives of workers in low-wage jobs in the United States.

TALKING POINTS

Here are a few talking points to help you summarize this chapter for family and friends without giving a lecture.

1. Industrial and organizational psychology is the science of behavior and mental processes in the workplace.
2. The tests and interviews that employers use to select employees are meant not just to choose the best candidates but also to find people who will be the "best fit" in their organizations.
3. To get the fairest picture of employees' job performance, some organizations collect ratings not just from their supervisors but also from their peers and subordinates.
4. It is illegal for employers in the United States to base hiring or firing decisions on any criterion (such as gender or ethnicity) unrelated to job performance.
5. Job satisfaction is not always related to salary; other factors—such as fair treatment and a sense of control at work—can be at least as important.
6. Many organizations have adopted family-friendly policies such as flextime to help reduce work-family conflict and increase job satisfaction.
7. Stress and lack of perceived control can be at the root of employee theft and workplace aggression.
8. Autonomous work groups supervise themselves and can be at least as productive and satisfied as groups that receive closer supervision.

SUMMARY

Our eyes, working with our brains, allow most of us to see the world in three-dimensional depth and in full color, but some people have a condition that leaves them unaware of half of that world. Even though their eyes work properly, when these people look at a nice round pizza, they see only half a pizza. They are not suffering from a mental illness of the kind we describe in the chapter on psychological disorders, but they most definitely have a problem in their brains. Understanding what the problem is, exactly where it is, and how it affects a person's behavior and mental processes takes us into the realm of neuropsychology, *which is the focus of this chapter.*

Something was wrong with Max. He put away his car keys, his wallet, and a pair of dress shoes in their usual places, but when he tried looking for them later, he had no idea where they were. "You're just getting forgetful," his wife teased. But at breakfast one day, he used a piece of bacon to stir his coffee. Then, mistaking a candle on the table for a glass of juice, he tried to drink it, and he used a pancake as a napkin, wiping his mouth with it before placing it carefully on his lap. He seemed puzzled by these mistakes. His wife took him to a doctor. Suppose you were that doctor. How could you determine what was wrong with Max? You would have many possibilities to consider. Maybe he is choosing to do silly things just to annoy his wife. But if he is not acting oddly on purpose, just where does the problem lie? Perhaps something is amiss in his brain. The problem might reside somewhere in his memory systems, but it might also be in the realm of attention or some other psychological function. Of course, the problem might be something less specific. Perhaps he has just been working too hard or is having a reaction to a medication or some sort of dietary deficiency. He might be experiencing depression, or maybe an unrecognized infection is affecting his ability to remember and concentrate. In this chapter, we explore *neuropsychology,* a subfield in which specially trained psychologists study patients such as Max in an effort to pinpoint the nature and cause of a wide variety of puzzling behavioral and psychological problems. We will describe how this subfield developed, what it has revealed about the relationship between brain functions and psychological functions, and how neuropsychologists study patients on a case-by-case basis. We will also describe some of the most interesting examples of what can go wrong in the brain and how these problems can affect people's thoughts, actions, and abilities.

Foundations of Neuropyschology

Neuropsychology is the subfield of psychology whose goal is to explore and understand the relationships among brain processes, human behavior, and psychological functioning. *Neuropsychologists* are interested in how brain systems, and disruptions of those systems, affect a wide range of human abilities, including cognitive functioning (such as language, memory, attention, mathematical, and visual-spatial skills), motor functioning (such as walking or threading a needle), emotional functioning (such as the ability to express emotions and understand other people's emotional expressions), and social functioning (such as daily interactions with others). They are interested, too, in how dysfunctions in the brain relate to changes in personality and to the appearance of psychological disorders such as depression.

The field of neuropsychology rests on two main assumptions. The first is that many complicated mental tasks, such as memory or decision making, involve numerous subtasks that can be tested and studied separately (Lezak, Loring, & Howieson, 2004).

neuropsychology The subfield of psychology whose goal is to explore and understand the relationships among brain processes, human behavior, and psychological functioning.

For example, as described in earlier chapters, the ability to form a new memory usually requires a person to be awake, to pay attention, to receive sensations, to perceive those sensations, to form mental representations of that information, to be motivated to remember the information, and to have the language or other verbal skills necessary to express the information when it is retrieved from memory. If any of these subtasks fails, a person's memory would appear to fail in any number of everyday situations. With this assumption about subtasks in mind, neuropsychologists must not only figure out what complicated mental tasks a person can and cannot do but also identify the failure of one or more subtasks that may be at the root of the problem.

The second main assumption of neuropsychology is that different psychological processes are controlled by different brain regions or by different combinations of brain regions (Fodor, 1983; Heilman & Valenstein, 2003). Neuropsychologists use this assumption to draw conclusions about each patient they examine. After deciding what psychological processes are impaired, they work backward to infer what brain region or combinations of regions may not be working properly. This "working backward" approach is valuable, because many kinds of brain damage or disease are too subtle to be identified by physical examination or by various brain-scanning procedures (Nadeau & Crosson, 1995).

Using these two main assumptions, some neuropsychologists conduct research on how the human brain controls and organizes separate parts of complicated mental activities. These scientists, known as *experimental neuropsychologists,* most often study people with brain damage, but they sometimes do research on people with normal brains too. Their aim is to add to our knowledge of brain functioning among people in general. **Clinical neuropsychologists** use this knowledge to try to understand the problems that appear in particular individuals such as Max. They look for the best way to examine each person so as to determine the likelihood of brain damage or dysfunction, what psychological processes are impaired, exactly how they are impaired, and which are still operating properly (Heilman & Valenstein, 2003; Lezak, Loring, & Howieson, 2004; Scott, 2006). Most clinical neuropsychologists are to be found in hospitals and other health care settings, where they work with physicians to test people with brain damage.

For example, Max's physician decided to have him tested by a clinical neuropsychologist, who showed Max a long series of simple drawings of common objects and asked him to name each one. Experimental neuropsychological research on large numbers of people provided *norms* that told her what kind of performance she could expect on this test from people of Max's age and educational background. She could then compare his performance to these norms. As you might expect, Max's responses were not normal. For example, looking at the drawing of a pencil, he said he saw "a long, narrow protrusion of some kind." He called a paper clip "an object curling into itself." For eyeglasses, he said, "That's two circular devices suspended together." Clearly he was not naming things well—but why? Could his vision be bad? No, because he could correctly read words even when they were in small print. He could also produce reasonably accurate copies of the drawings, even though he could not always name the objects in them. This meant that he had sensed and perceived the drawings' shapes, angles, and spatial relationships. Did Max have a general problem with memory, as his wife had suggested? To test that idea, the neuropsychologist read him lists of words and later asked him to recall them. He did about as well on this memory test as most people of his age and level of education, so his memory seemed normal. The neuropsychologist next considered whether Max was no longer able to understand the concepts represented in the drawings. But this possibility was ruled out when he correctly defined the words *pencil, paper clip,* and *eyeglasses*. So he knew what these objects were, and when examples of them were placed into his hands while he was blindfolded, he could name them instantly. So Max could recognize these objects through his sense of touch but not through his sense of vision.

Why? The neuropsychologist concluded that Max still had normal function in brain areas that process basic visual sensations but that something was wrong in the brain regions that normally convert those sensations into recognizable visual

clinical neuropsychologists
Neuropsychologists who use tests and other methods to try to understand neuropsychological problems and intact functions in individual patients.

perceptions. Research on the brain told the neuropsychologist that this problem, called a *visual agnosia* (pronounced "ag-NOH-zhuh"), can occur when parts of the temporal lobes on both sides of the brain are not working properly (Bauer & Demery, 2003; Spalletta et al., 2007). Max's physician used that information to focus his medical care on those brain regions.

Max's case illustrates several important aspects of what neuropsychologists have learned about how the brain operates. Let's review some of what they have discovered and how these discoveries occurred.

A Brief History of Neuropsychology

Max's case shows **localization of function**, the idea that specific psychological functions can be affected by damage to specific brain areas. This concept probably seems obvious to you, especially if you have read about the brain in the chapters on biological aspects of psychology, sensation, and consciousness. But this "commonsense" notion was once a matter of considerable debate (Tyler & Malessa, 2000). In fact, for centuries, philosophers and scientists had been speculating about the role of different brain areas in different psychological functions (Eling, 2008; Kaitaro, 2001).

Early in the 1800s, for example, the dominant view was that the brain worked more or less as a single organ, such that no particular part was any more important than any other part in the control of mental life. An anatomist named Franz Gall disagreed with this view, arguing instead that particular brain areas controlled particular aspects of cognitive functioning (Zola-Morgan, 1995). Gall's claim turned out to be correct, and his legacy would be more widely honored except for the fact that Gall also mistakenly believed that brain areas, like muscles, get bigger as people use them. He believed, too, that each brain area is associated with certain behavior patterns or personality traits, such as honesty or love or aggressiveness. Finally, Gall assumed that as brain areas grew larger, there would be corresponding bumps in the skull just above them. After creating a map showing which brain areas were supposedly controlling which traits, he thought he could assess a person's psychological makeup by measuring the bumps on the skull. Gall's approach, which was known as *phrenology,* was a hit with the public because it appeared to offer a simple way measure personality (Benjamin & Baker, 2004). But assessing personality by feeling people's skulls was a far-fetched and easily refuted notion that led Gall's scientific colleagues to dismiss virtually everything he said about the brain's role in psychology. In fact, the ridicule heaped on phrenology tended to taint all theories about localization of function.

In 1861, though, everything changed. It was then that a famous and widely respected French surgeon, Paul Broca, examined a hospitalized patient whose leg had a serious deep-tissue infection called gangrene. (In this era before antibiotics, gangrene often required amputation.) It so happened that many years earlier, this patient had had a **stroke**—the official medical term is **cerebrovascular accident**, or CVA—a condition in which one of the blood vessels to the brain is blocked, causing permanent damage to the brain. The stroke left him unable to say anything but the word *tan,* which became the staff's nickname for him. Despite his speech difficulties, Tan could apparently understand spoken language because he easily followed verbal commands. Before anything could be done about Tan's gangrene, he died, and Broca ordered an autopsy. It showed a small **lesion**, or area of damage, in the left frontal lobe of Tan's brain (see Figure 20.1). Broca wondered if this lesion was related to Tan's speech problems, and if so, how such a small lesion could cause such a major and specific problem. Not long afterward, Broca requested an autopsy on another patient who had had language problems similar to Tan's and discovered a brain lesion in the same place as Tan's.

If lesions in this particular spot were somehow linked to these patients' speech disorders, the previously dismissed idea of localization of function might actually be correct. Indeed, a particular brain area could be involved in controlling a particular function such as speech (Broca, 1861, 1865). This is precisely what Broca proposed

localization of function The idea that specific psychological functions can be affected by damage to specific brain areas.

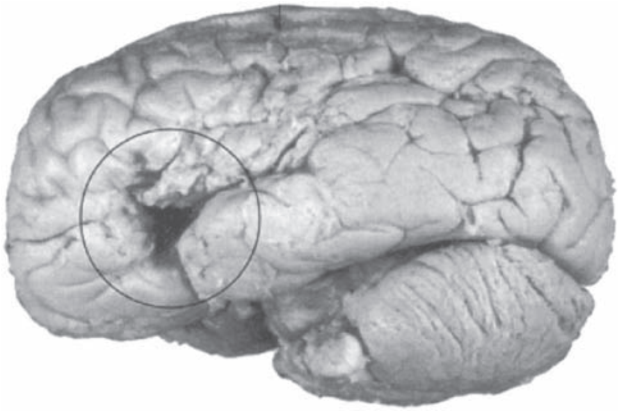
cerebrovascular accident (stroke) A loss of blood supply to some part of the brain, resulting in disruption of some aspect of behavior or mental processes.

lesion An area of damaged tissue in the brain.

FIGURE 20.1

Tan's Brain

When Tan died, Paul Broca discovered severe damage in the left frontal lobe of the cerebral cortex, just in front of the primary motor cortex. This site, now known as *Broca's area,* is involved in the ability to produce normal speech.



From Corsi, P., ed. The Enchanted Loom. New York: Oxford University Press, 1991. Musée Dupuytren, Paris. Photo courtesy of Dr. Jean-Louis Signoret

when he shared his observations in a lecture to the Anthropological Society of Paris. And because, unlike Gall, Broca held such high status in the scientific community, his support of localization of function made it a respectable idea. In fact, it created an upsurge of scholarly interest in localization of brain function that is still seen today. The resulting explosion of brain research that occurred in the past century and a half has not only confirmed localization but established that localization is more complex than anyone in Broca's time would ever have guessed.

Modules and Networks

More recent approaches to localization of function have introduced the idea that the brain is organized into discrete regions called **modules**, each of which adds its own unique kind of analysis of the information it receives (Fodor, 1983; Uttal, 2003). According to this *modularity* view, each module, located in a unique brain area, acts somewhat like a circuit board in a computer. That is, a module does not itself "control" any particular function, but it adds a needed piece to complete a larger puzzle that allows speech or some other function to occur. The analysis performed by a particular module can be used in many kinds of brain functions. And each brain function—whether it is detecting the edges of an object or making a decision about something—is accomplished through the support of a different team, or *network,* of modules (Mesulam, 1990). It is as if the brain were the head of a company with a vast array of employees, each with a specific skill, which can be organized and reorganized from one moment to the next into many different work teams to perform many different tasks.

Speaking and understanding language, for example, involves a network of modules in several brain areas (Ross, 2010). This means that damage to any part of the network will affect a person's language ability in some way, but the exact effect will depend on which part of the network is damaged. In Tan's case, for example, the lesion in his left frontal lobe disrupted his ability to speak but left him with the ability to understand what was said to him.

The brain regions underlying language are a particularly good example of a network that uses several modules. One of the interesting consequences of a system that is organized in this way is the potential for a *disconnection syndrome.* Such syndromes occur when various modules in a network, though themselves intact, are prevented from interacting (Geschwind, 1968). A classic example is *alexia without agraphia,* which literally means inability to read while still being able to write (Imtiaz, Nirodi, & Khaleeli, 2001; Sheldon, Malcolm, & Barton, 2008). The brain damage shown in Figure 20.2 could produce this kind of disconnection syndrome. Here, there is damage to the left occipital lobe, causing loss of vision, but only for what is on the right side of the visual field. The patient can still see the left side of the visual field. However, there is also damage to part of the corpus callosum, which connects the left and right hemispheres of the brain. This particular part of the corpus callosum normally allows

modules Regions of the brain that perform their own unique kind of analysis of the information they receive.

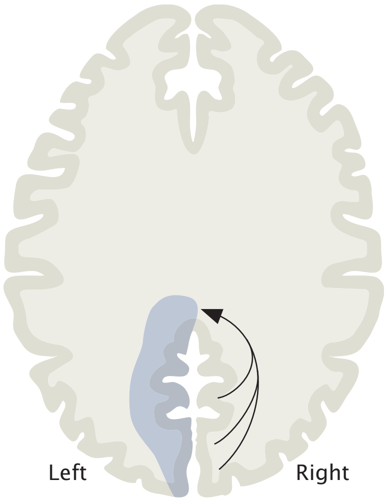


FIGURE 20.2

Alexia Without Agraphia

This is a classic example of a disconnection syndrome. Brain damage (in darker blue) has occurred in the left occipital lobe and part of the corpus callosum. As a result, no visual information can enter the left hemisphere. The left hemisphere brain regions that create writing are intact, so these patients can write. But because feedback from the visual system cannot get back to the language processing systems of the left hemisphere, the patients cannot read what they have written.

visual information from the left side of the world to cross from the right hemisphere into the left hemisphere, but now this pathway is blocked. Because the language-producing regions of the left hemisphere are intact, the person can still talk and write normally but can see only what lies in the left visual field. That information goes to the right hemisphere, but because it cannot cross from there into the left hemisphere, where most language functions reside, people with this kind of disconnection syndrome cannot read what they write. In effect, the visual processing of the words is disconnected from the brain regions that are needed to understand the meaning of the words.

Lesion Analysis

Much as Broca did so long ago, experimental neuropsychologists today still study localization of function by looking at the results of brain damage. This aspect of their work is sometimes called *lesion analysis* (Aharonov et al., 2003). To get an idea of how lesion analysis works, suppose that a man with normal mathematical ability has a stroke that damages his left parietal lobe (see Figure 3.15 in the chapter on biological aspects of psychology for the location of this area). Afterward, like other people with similar brain damage, he can no longer perform mathematical calculations. Do these observations confirm that the ability to do math is localized in the left parietal lobe in human brains? Possibly, but not necessarily. Critical thinking by experimental neuropsychologists leads them to consider other possibilities too.

For example, we have already seen that complex psychological functions often require the cooperation of many modules in different brain areas. So although mathematical ability may well be impaired by damage to the left parietal lobe, it may also be affected by damage to other regions in the "mathematics" network. Experimental neuropsychologists explore this possibility by studying the changes in math ability seen in large numbers of people with damage to many different regions of the brain. If they find that math ability is affected by left parietal lobe damage but nowhere else, they would be more confident in asserting that mathematical ability is localized in that area. If they find that damage in other areas also affects math ability, they would realize that this ability is not as localized as it might at first seem.

But lesion analysis must also address the question of just what function it is that has been damaged. For example, doing a mathematical calculation might require you to use several kinds of abilities, such as recognizing numbers and symbols, remembering the rules of addition or multiplication, keeping several numbers in your head as you do calculations, and being able to read or hear the math problem and report your answer. So if a brain lesion makes it hard for you to talk, you would not be able to answer the question "How much is 2 plus 2?" But this may not mean that there is anything wrong with your mathematical ability.

To help figure out exactly what problems a brain-damaged patient actually has, experimental neuropsychologists look at a complex mental task, such as reading or doing math, and—in light of research from sensation, perception, and cognitive psychology—try to identify all the abilities that a person's brain must combine to succeed at that task. They then try to determine which of these abilities are actually separate, or *dissociated,* perhaps because they are based in different brain modules in particular brain regions. One way to establish a dissociation between abilities is to study which components of a mental task are affected by which kinds of brain damage. An important example of dissociated abilities is described in the chapter on biological aspects of psychology. Damage to a particular area in the left frontal lobe disrupts a person's ability to speak fluently but leaves the person able to understand most of what others say. Damage to a different area in the left temporal lobe does the opposite, leaving the person able to speak easily but unable to understand what others are saying. We will discuss these conditions again later in this chapter. ("In Review: Foundations of Neuropsychology" summarizes milestones in the history of neuropsychology.)

IN REVIEW Foundations of Neuropsychology

Principle	Main Figure or Era	Key Ideas
Localization of function	Franz Gall, early 1800s Paul Broca, mid-1800s	The idea that a specific psychological function could depend on a specific brain area
Modularity	Late 1900s	A revision of localization in which each brain area performs different, unique computations, which contribute to various psychological functions
Networks	Late 1900s	A perspective suggesting that different complex psychological functions rely on unique combinations of brain modules
Lesion analysis	1800s to the present	An approach to experimental neuropsychology in which psychological functions are linked to particular brain areas by studying patients with damage to those areas and comparing these people with people who have damage elsewhere or no damage

1. A person who studies individual patients to determine what kind of brain damage each one happens to have is called a ____________.
2. The case of "Tan" helped establish the principle of ____________.
3. In alexia without agraphia, the brain areas that control reading and writing are intact but cannot interact. This condition is called a ____________.

Neuropsychological Assessment

So far we have discussed how the brain is organized and how neuropsychologists go about studying ways in which its functioning is related to behavior and behavior problems. Let's now consider how they decide when a person has such problems. Consider memory, for example. Everyone forgets things sometimes, even such familiar things as your best friend's phone number, the name of your roommate's brother, or where you left your car keys. But how much forgetfulness is normal and how much does it take to be labeled as excessive or problematic?

LINKAGES What psychological tests are used in diagnosing neuropsychological disorders? (a link to Cognitive Abilities, p. 376)

To answer this question, neuropsychologists typically conduct a **neuropsychological assessment** by giving patients a large number of tests designed to measure a wide range of mental functions, such as general intelligence, memory, reading, motor coordination, naming pictures, and finding targets in a visual display. Some neuropsychologists prefer to use an individualized set of assessments uniquely tailored to each patient. In this way, they hope to measure the specific problems that a particular patient is most likely to have. In other cases, patients are given a standardized test battery, which includes a predetermined set of tests that are designed to complement one another and comprehensively address all aspects of psychological functioning. Many such test batteries have been carefully prepared and validated. Among the best-known examples are the Halstead-Reitan Battery, the Wechsler Adult Intelligence Scale, and the Luria-Nebraska Neuropsychology Battery. Standardized batteries offer the advantage of giving each patient the same tests in the same way, but they don't allow the neuropsychologist to tailor testing to focus on a patient's particular problems or unique situation. Accordingly, most clinical neuropsychologists start with a standard test battery and then administer additional tests that are particularly relevant to each case.

By giving a variety of tests, the clinical neuropsychologist can get a glimpse into many different aspects of a person's psychological functioning and also measure each area separately. Analyzing the overall pattern of results may help pinpoint where the difficulties in the brain may lie. But the results of neuropsychological testing, like the results of personality testing, intelligence testing, and academic testing, must be interpreted with caution. Many factors, such as age, education, and cultural background, can affect a person's performance on neuropsychological tests. With this in mind, each patient's performance on these tests must be compared with established averages, or norms. These norms are based on the test performance of thousands of people who are of the patient's own age, educational level, and cultural background but who have no known brain damage. Norms also give clinical neuropsychologists an idea of how often normal people's scores vary from the average and by how much. Having this information helps establish whether a score that looks deviant at first glance is actually

neuropsychological assessment Testing a patient's intelligence, memory, reading, motor coordination, and other cognitive and sensory functions in an effort to locate problems in the brain responsible for neuropsychological symptoms.

as unusual as it seems. Norms can also reveal when what seems like a minor deviation from the average is actually quite unusual and indicative of a potential problem.

Training for Neuropsychology

A large part of a clinical neuropsychologist's training is focused on learning about many different kinds of neuropsychological tests, how to administer and score them, and how to combine and interpret their results so as to reach the most accurate conclusions about patients' problems and the likely source of those problems (Boake, Yeates, & Donders, 2002). Neuropsychologists typically train in graduate school, earning a Ph.D. degree in clinical psychology with a special focus on neuropsychology and the many topics related to it. Before they can get a license to practice on their own, however, they must complete an internship. The internship usually includes a year or more of neuropsychological practice performed under the close supervision and mentoring of a licensed clinical neuropsychologist, typically in a university hospital setting. Once licensed, clinical neuropsychologists tend to be hired by health facilities where there is a need for testing patients for possible brain damage. Many neuropsychologists are employed directly by a hospital; others join specialty clinics where they work closely with physicians who focus on the diagnosis and treatment of brain disorders. Some may work in highly specialized facilities that offer programs focusing only on patients who have had a cerebrovascular accident or brain trauma. Experimental neuropsychologists are usually employed by universities, where they teach students, conduct their own research, and participate in testing patients as time permits.

Mechanisms of Brain Dysfunction

We have been talking a lot about brain damage, and perhaps you are wondering how brains get hurt.

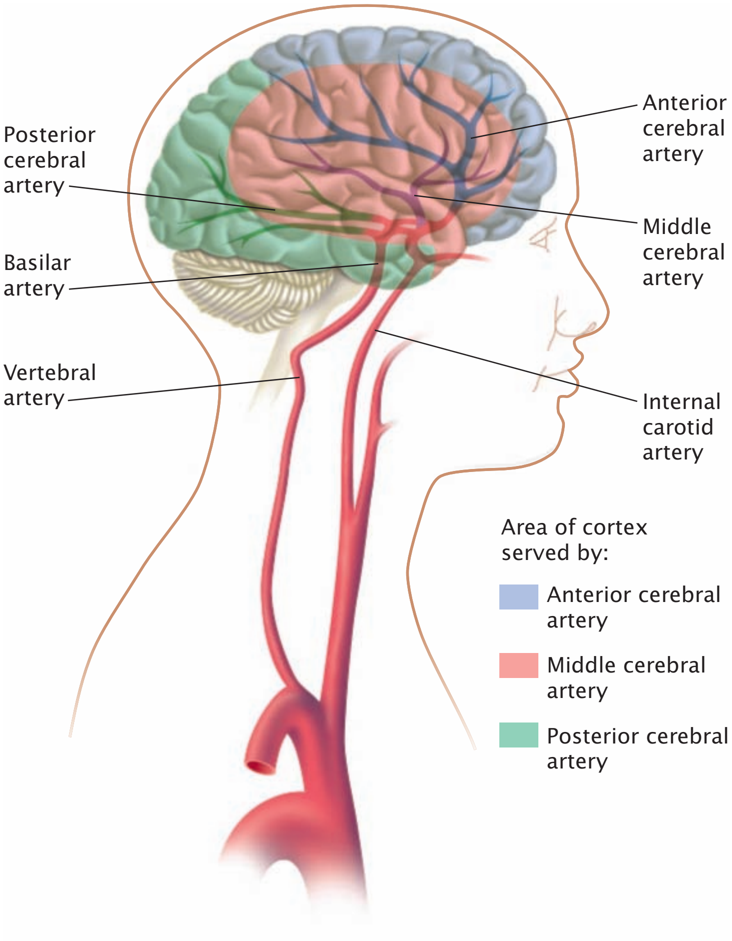
Cerebrovascular Accidents

As you may have guessed by now, cerebrovascular accidents (strokes) are a common source of brain damage. The brain receives all the oxygen, sugar (glucose), and other nutrients it needs from the rich supply of blood flowing through it (see Figure 20.3). But brain cells cannot store much of this energy, so they must have a supply of fresh blood at all times (Acker & Acker, 2004). If a vessel bringing blood into some part of the brain becomes blocked, the brain tissue in that part of the brain will die, and whatever function that part of the brain usually did will be disrupted or destroyed (Caplan, 2004, 2005). When someone's behavior or mental processes are affected by brain damage from a loss of blood supply, the person is said to have had a cerebrovascular accident. Even very tiny CVAs can cause disabling symptoms if they take place in vital brain areas, but strokes in less vital areas may cause few, if any, symptoms.

Strokes can be quite dangerous. In fact, they are the third-leading cause of death in the United States (Heron et al., 2009). They tend to occur as people get older, but young adults and even children can have them. Unlike heart attacks, in which blood flow to the heart muscle is disrupted, a stroke usually involves little or no pain because there are no pain receptors in brain tissue. So a stroke victim may not immediately realize that anything is wrong. The resulting delay in seeking medical attention can be costly, because treatments that can help reduce the effects of a stroke must be administered as soon as possible after the stroke occurs (Hjelmblink, Holström, & Kjeldmand, 2010).

Like explosions that break windows a block away, strokes affect not only the area in which brain tissue has died but also the surrounding area. Fortunately, if cells in the area around a stroke have not actually died, they may start working again (Liebeskind, 2010). As a result, some people recover all or part of their lost functions. The amount of recovery depends on many factors, including the quality and speed of medical

FIGURE 20.3
The Brain's Blood Supply
TRY THIS Blood reaches the brain either through the carotid arteries on either side of the neck or through vertebral arteries entering through the base of the skull. Once in the brain, these arteries branch into the anterior cerebral artery, the middle cerebral artery, and the posterior cerebral artery. Each artery provides blood to specific brain areas. Consequently, a blockage in a particular blood vessel damages a specific, predictable part of the brain. Review the chapter on biological aspects of psychology to remind yourself of the functions associated with each area of the cerebral cortex. Then make a list of the functions that would most likely be affected by blockage in each of the arteries shown in this figure.



treatment, how large the stroke is and where it is located, the health of the remaining blood vessels and brain tissue, the quantity of salvageable tissue, the degree to which the remaining nervous system can reorganize along its original lines, and the kinds of rehabilitation programs undertaken after the stroke (Cramer, 2008; Frizzell, 2005; Heiss & Teasel, 2006; Kelley & Borazanci, 2009). To help the brain heal itself, some scientists are experimenting with chemicals that stimulate existing cells to grow; others are inserting stem cells into the brain to replace damaged tissue. As described in the chapter on biological aspects of psychology, though, restoring functions lost to a stroke takes more than just restoring the cell population in damaged brain areas. The new cells must also somehow be influenced to reestablish the right connections with other brain cells (Kalluri & Dempsey, 2008; Liu et al., 2009).

Traumatic Brain Injury

Another major cause of brain damage is **traumatic brain injury**, also known simply as **trauma** (Okonkwo, 2003). Trauma creates an impact on the brain, as when a person's head is struck by a baseball bat or a bullet or when during an accident the head moves suddenly or is thrown violently against some object. Traumatic events such as these can cause damage because the brain is not firmly attached to the skull. Instead, it floats within it, suspended in a bath of **cerebrospinal fluid**. So when the head is struck or violently accelerates or decelerates, the soft globe of brain bounces back and forth inside the skull, bumping up against bone and causing nerve fibers in many areas to stretch and tear.

The amount of brain damage resulting from trauma depends greatly on the amount of force involved in such situations. Further, unlike in strokes, where only the area in and around a disrupted blood supply is likely to be affected, the damage and disruption caused by trauma may be widespread. So whereas stroke patients may show very specific kinds of

traumatic brain injury (trauma) An impact on the brain caused by a blow or a sudden, violent movement of the head.

cerebrospinal fluid A clear liquid that surrounds and buffers the brain against vibration.

neuropsychological deficits, sometimes with striking dissociations between functions that are lost and those that are preserved, people with head injuries may display deficits that are far more diffuse, harder to specify, and involve many aspects of functioning (Wade, 2004), including cognitive and psychiatric problems (Malojcic et al., 2008; Schwarzbold et al., 2008). This may explain why we know much more about the neuropsychological symptom patterns that follow strokes than we do about those following brain traumas.

Neurodegenerative Diseases

Unlike the sudden symptoms that result from brain damage caused by stroke and trauma, other brain problems develop gradually. These more slowly developing symptoms often appear because **neurodegenerative diseases** are causing *neurodegeneration,* the gradual process of damage to brain cells (Mayeux, 2003). Three of the most prominent examples of neurodegenerative diseases are Alzheimer's disease, Parkinson's disease, and Huntington's disease. Each type of neurodegenerative disease affects a particular kind of brain cell or cells in a particular part of the brain, causing them to be the first to stop working properly (Cummings, 2003) and leaving the victim without the mental or physical functions those cells had once supported. The pattern of symptoms resulting from each neurodegenerative disease is different enough that neuropsychological assessment of a patient can lead to a diagnosis of which disease is affecting that patient (Brun, 2007; Miller, 2007).

Some kinds of neurodegeneration appear to be caused by infections, nutritional deficiencies, or genetic abnormalities, but despite intense research, we are still not sure about the specific causes of most such diseases. ("In Review: Mechanisms of Brain Dysfunction" summarizes the major causes of brain injury and dysfunction.)

IN REVIEW Mechanisms of Brain Dysfunction

Brain Problem	Onset	Underlying Process	Symptoms
Cerebrovascular accidents (stroke)	Sudden	Blood flow is blocked in some part of the brain.	Specific to the area of the brain that is destroyed
Traumatic brain injury (trauma)	Sudden	Brain moves back and forth inside the skull.	Often nonspecific, diffuse
Neurodegenerative disease (neurodegeneration)	Gradual	A subset of neuron cell types becomes diseased and stops working properly.	Specific to the types of brain cells affected

1. The brain floats in a bath of ____________ inside the skull.
2. The brain needs a constant flow of fresh ____________ at all times.
3. Cerebrovascular accidents rank as the number ____________ cause of death in the United States.

neurodegenerative diseases Conditions in the brain that result in a gradual loss of nerve cells and of the cognitive or other functions in which those cells are normally involved.

syndrome A pattern of symptoms associated with a specific disorder.

amnestic disorders Neuropsychological disorders that involve memory loss.

Neuropsychological Disorders

Let's now take a closer look at the **syndromes**, or patterns of symptoms, that clinical neuropsychologists typically see in patients who have suffered stroke, trauma, or neurodegenerative disease. These syndromes are referred to as *neuropsychological disorders* and include amnestic disorders, consciousness disturbances, perceptual disturbances, disorders of language and communication, disorders of movement, and disorders involving dementia.

LINKAGES What disorders are caused by damage to brain areas involved in memory? (a link to Memory, p. 272)

Amnestic Disorders

Amnestic disorders involve memory loss (often referred to as *amnesia*). Specific concerns about memory problems often bring people to clinical neuropsychologists for evaluation. These people are concerned partly because they rely heavily on memory, and any threat to its integrity can be extremely upsetting. But patients also tend to highlight memory problems because we all have a tendency to interpret almost any psychological deficit as being related to memory (Lezak, Loring, & Howieson, 2004). As in Max's case, for example, people who begin having trouble naming objects may say they are "forgetting" words, even though the problem could actually be one of language or visual recognition. Many older individuals, too, seek neuropsychological assessment because of worry that even minor forgetfulness might be an early sign of Alzheimer's disease. We discuss Alzheimer's in the section on dementia, but memory loss can occur in other neuropsychological syndromes too (Lucas, 2005).

For example, the ability to create new long-term memories can be impaired by damage in the brain's medial temporal lobes ("medial" means toward the middle of the brain), especially in the hippocampus (Ando et al., 2008; de Haan et al., 2006; Rosenbaum et al., 2008). Consider the famous case of H.M. (Scoville & Milner, 1957; Squire, 2009). In 1953, this 27-year-old man's epilepsy was so severe that he underwent brain surgery in an effort to stop his seizures. The surgery removed parts of both his left and right temporal lobes, including parts of the hippocampus on both sides. This radical treatment ended his seizures, but it left H.M. with a dense amnestic syndrome that persisted until his death at the age of 82 in 2008 (Mackay, 2006; Squire, 2009; see Figure 20.4). Although he was able to recall most details of his life from before the

FIGURE 20.4

H.M.'s Brain Surgery

H.M. underwent surgery that removed the hippocampus, amygdala, and part of the association cortex from both temporal lobes. As shown in these MRI scans comparing an intact brain with H.M.'s brain after surgery, H.M. had some hippocampus (H) but no entorhinal cortex (EC). In this image, (V) refers to the lateral ventricle, (f) refers to the fornix, (PH) refers to the parahippocampal cortex, and (Cer) refers to the cerebellum.

Coronal sections of H. M.'s brain

Courtesy Dr. Suzanne Corkin, Massachusetts Institute of Technology. Copyright © 1997 Society for Neuroscience. J. Neurosci., May 15, 1997, 17(10):3964-3979 surgery, he had difficulty forming new memories. In other words, as discussed in the memory chapter, he had **anterograde amnesia**. When he met someone new, he was unable to recall the meeting, so the person seemed to be a stranger no matter how many times they met again. Similarly, new words he heard over the years—such as *computer, videotape, cell phone,* and *Jacuzzi*—never made it into his vocabulary. He wasn't even able to remember that time was passing, so he had few clues that he was getting older; to a great extent, he was mentally stuck in the 1950s.

Many of H.M.'s other mental capacities remained largely intact, however, providing a striking example of the dissociation that can occur between abilities lost and those retained after brain damage. His language function remained good; he recognized objects; he thought and reasoned; he remained intelligent, pleasant, and sociable; and he carried on very normal-sounding conversations. But even he was quite aware of his memory problem. He put it as follows: "Right now, I'm wondering, have I done or said something amiss? You see, at this moment everything looks clear to me, but what happened just before? That's what worries me. It's like waking from a dream. I just don't remember" (Milner, 1970, p. 37).

H.M. was carefully studied for years, and the lessons learned from him have prompted research on memory loss in other people after medial temporal lobe damage. When other people have amnesia caused by damage to the hippocampus, just like H.M., they also have difficulty remembering the new experiences or events of their lives. But also like H.M., it turns out that these individuals can still learn new skills and habits as a result of their new experiences. When they do a task over and over, they get better at it, meaning that they do form some kind of a memory. Nonetheless, they have no awareness of this learning and do not recall the experiences that led to it (see Figure 20.5).

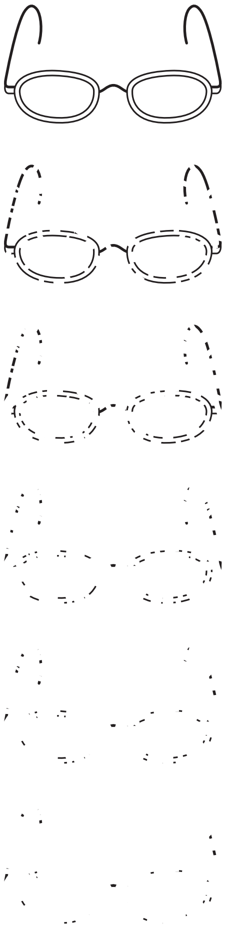

FIGURE 20.5

Memory Without Awareness

People with amnesia due to medial temporal lobe damage may still learn from the experiences that they otherwise cannot recall. These stimuli show degraded versions of a drawing. Using stimuli similar to these, participants with amnesia first saw a very degraded version, then one less so, then another clearer one, and so on until they could name the item. Patients with amnesia were able to name items earlier if they had seen them before, even when they could not recall having seen them.

Anterograde amnesia and other amnestic syndromes can be caused by events other than surgery in the hippocampus and medial temporal lobe. For example, certain brain infections, such as herpes encephalitis (Ando et al., 2008; Baringer, 2008), tend to damage these same parts of the brain and create an amnestic syndrome similar to that of H.M. Cerebrovascular accidents, too, can sometimes damage these regions, though they are usually on just one side of the brain, so the amnestic syndrome may not be as noticeable. Finally, as described later, these regions, and the memory functions they normally perform, can also be impaired by Alzheimer's disease (Wolk et al., 2010).

The hippocampus is not the only structure involved in memory. For example, as described in the chapter on biological aspects of psychology, the thalamus processes information from all the senses except smell and sends it on to the cerebral cortex for further processing. But the medial dorsal (middle and top) region of the thalamus is also part of the brain's *limbic system,* an interconnected set of structures that includes the hippocampus (see Figure 20.6). The medial dorsal thalamus is seldom damaged by trauma or stroke, but it is often damaged when people have **Korsakoff's psychosis**, also known as **Korsakoff's syndrome** (Butters, 1981), a condition in people whose thiamine (vitamin B1) is depleted by inadequate nutrition or alcoholism. Running low on thiamine is dangerous because this vitamin is needed to process glucose (sugar) for energy. Nerve cells of the medial dorsal thalamus are especially dependent on this function of thiamine (Marti, Singleton, & Hiller-Sturmhofel, 2003), so if thiamine deficiency is severe, nerve cells there are more likely to die than in other brain regions (Kumar, 2010; Vemuganti et al., 2006). The result is anterograde amnesia with an additional unusual feature: **confabulation**, or the creation of false memories, both spontaneously and in response to questions (Borsutzky et al., 2008; Butters, 1981). These individuals believe that they have had experiences that they have not actually had, and they "recall" them as if they were real. Research with other confabulating patients suggests that this condition may also occur following damage to the inferior medial prefrontal system (Turner et al., 2008). Other amnestic syndromes do not usually produce confabulation, so when clinical neuropsychologists test patients with severe anterograde amnesia and find confabulation too, they often suspect medial dorsal thalamic amnesia or inferior medial prefrontal amnesia.

anterograde amnesia A loss of memory for events that occur after a brain injury.

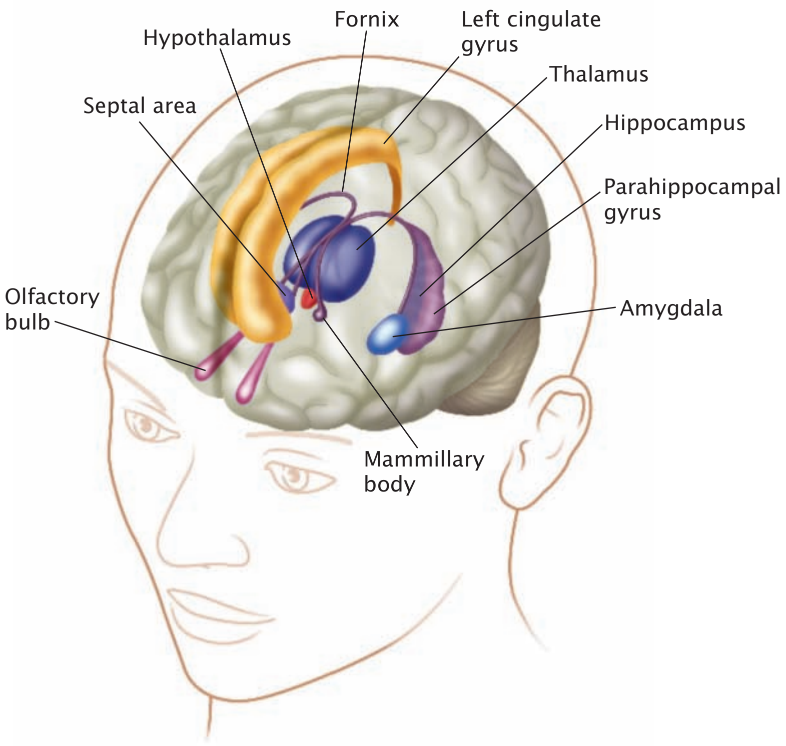
Korsakoff's psychosis (Korsakoff's syndrome) An amnestic condition in people whose thiamine (vitamin B1) level is depleted by inadequate nutrition or alcoholism.

confabulation A characteristic of some neuropsychological disorders in which patients report false memories.

FIGURE 20.6

The Limbic System

A number of closely connected structures form the limbic system, which controls many aspects of motivation and emotion.



Consciousness Disturbances

Sometimes problems in the brain can create **consciousness disturbances**, which impair people's ability to be fully aware of the world around them (Bernat, 2009). One such problem occurs when there is disruption or damage to the **reticular formation**, also known as the *reticular activating system,* or *RAS*. The RAS is a long, tubelike structure that begins in the base of the brain and extends upward, eventually splitting into two halves that reach into both sides of the thalamus. As its name implies, the RAS normally serves to increase and decrease arousal in the rest of the brain and is partly responsible for our daily cycles of wakefulness and sleep (Izac & Eeg, 2006). If the RAS is severely damaged, the result can be an unconscious state known as a *coma*. People with lesser amounts of RAS damage may enter a *persistent vegetative state* (*PVS*) (Bekinschtein et al., 2005). Unlike patients in comas, people in a PVS may open their eyes and appear to wake up during the day and close their eyes and appear to sleep at night. They may also show a wider array of automatic movements than coma patients. For example, when food is put the mouth of someone in a PVS, chewing movements may occur, and sounds and touches may sometimes trigger facial expressions. But though EEG and fMRI scans show activity in some areas of these individuals' brains—including activity in speech-processing areas in response to familiar voices (Brenner, 2005; Eickhoff et al., 2008; Laureys, 2004; Magee, 2007; Schiff et al., 2005)—most patients remain unaware of their environment. The chances for recovery are often poor following significant damage to the RAS.

Even if the RAS is working properly to stimulate the rest of the brain, consciousness can be impaired if there are widespread disruptions in the functioning of both sides of the cerebral cortex, where other aspects of awareness are controlled (Stevens & Bhardwaj, 2006). Impairment of both sides of the cortex is most commonly caused by drugs such as alcohol or sleeping pills, but other causes include fever, seizures, chemical imbalances in the blood, hormonal disorders, and infections that have spread to the blood (Plum & Posner, 2000).

Other disturbances of consciousness have more complex and changing effects. People with **delirium**, for example, experience alternating periods of abnormally

consciousness disturbances Neuropsychological disorders in which there are impairments in the ability to be aware of the world.

reticular formation A collection of cells and fibers in the hindbrain and midbrain that are involved in arousal and attention.

delirium Periods of abnormally impaired or abnormally elevated levels of consciousness.

impaired consciousness and abnormally elevated levels of consciousness (Kahn et al., 2009; Torpy, 2008). The impairments in consciousness appear in many mental functions, usually including poor attention, poor memory, and disorientation. Elevated consciousness may appear as hallucinations (hearing sounds or seeing things that are not really there) or as episodes of mental agitation for no apparent reason. Indeed, a key feature of delirium is the rising and falling of consciousness (Plum & Posner, 2000). These patients may appear sleepy and "out of it" one minute and then far too attentive the next, as shown by reactions to every little sight and sound. Common causes of delirium include fever, poisons, infections that have reached the bloodstream, and the side effects of medication. Delirium can sometimes signal a medical emergency, but most of the time its psychological effects are not permanent. Delirium usually disappears when the underlying medical cause is corrected (Skrobik, 2009).

Neuropsychological testing of people in delirium is difficult (Milisen et al., 2006). Their attention and awareness can vary, sometimes dramatically, over the course of testing. In general, performance on almost any test is very poor, probably because patients with delirium cannot pay attention long enough or well enough to cooperate with the testing process. Indeed, their typical pattern of performance on neuropsychological tests is that there is no pattern—everything may look impaired.

Still other consciousness disturbances involve problems not in people's level of consciousness but in the nature or content of their consciousness. For example, a person may have a stroke that causes total paralysis of one side of the body, but the person may have no awareness that there is anything wrong. This condition is called *anosognosia* (pronounced "an-oh-sug-NOH-zhuh"), which means an absence of knowledge of disease (Langer, 2009). In such cases, it appears that brain damage causes not only an impairment in functioning but also an impairment in the ability to know about that impairment. This makes sense because the brain is the organ that we use to figure out when something is wrong. So if you have pain in your arm, sensory neurons tell the brain about it. But if the brain itself is hurt, it has nowhere to send its message.

People can have anosognosia with respect to a variety of problems, from paralysis to blindness to amputation of a limb (McGlynn & Schacter, 1989). It is also often seen in association with Alzheimer's disease (Pia & Conway, 2008). Anosognosia is more likely after damage to the right side of the brain (Nathanson, Bergman, & Gordon, 1952; Spalletta et al., 2007). Anosognosia is relatively common, occurring, for example, in more than 25 percent of all cerebrovascular accident cases (Starkstein et al., 1992). An unfortunate result is that these patients may not be motivated to get the prompt medical attention needed to limit the amount of damage that a stroke can cause. Anosognosia usually fades over time, but it may persist. When it does persist, it impairs patients' cooperation with rehabilitative treatments. They don't recognize that something is wrong, so they don't understand why treatment is necessary. There may be ways to improve awareness of neurological deficits, though. In one case, a man was unaware of the sudden and bizarre involuntary movements he had been making for several years. He could not see these movements, even when looking at himself in a mirror, but when watched himself on videotape, he instantly saw the problem (Shenker et al., 2004).

THINKING CRITICALLY

Can Someone Be Partially Paralyzed and Not Know It?

In anosognosia, a person denies any neurological deficit because there is no understanding that a problem exists. This phenomenon was first described long ago in relation to strokes that caused *hemiparesis,* a weakness or partial paralysis that affects just one side of the body (Babinski, 1914). Skeptics have argued that people with hemiparesis are still fully capable of knowing that they are partially paralyzed but that this knowledge would be so upsetting that they simply cannot admit it, even to themselves. According to this argument, anosognosia is not based on true unawareness but on the operation of an unconscious mental process similar to the ego defense mechanism that Freud called *denial* (see the chapter on personality).

What am I being asked to believe or accept?

Arguing against these skeptics are those who say that anosognosia occurs because the brain damage that causes hemiparesis also damages the parts of the brain that would allow the person to know that something is wrong. As a result, patients who seem unaware of hemiparesis or other problems are, in fact, truly unaware of them (Heilman, Barrett, & Adair, 1998; McGlynn & Schacter, 1989).

What evidence is available to support the assertion?

Those who believe that anosognosia is genuine unawareness point out that if it were the result of an ego defense mechanism, patients would deny any and all potentially upsetting deficits. Yet evidence from neurological examinations shows that some hemiparesis patients, for example, are aware that an arm is weak but not that a leg is weak (Berti, Ladavas, & Corti, 1996; Bisiach et al., 1986). Others are aware that they have a speech disturbance but not weakness in a limb (Bisiach et al., 1986; Breier et al., 1995).

Another problem with the ego defense mechanism argument is that anosognosia occurs much more often after right hemisphere brain damage, which causes left-side hemiparesis, than it does when left hemisphere brain damage causes right-side hemiparesis. It would seem that weakness on either side should be about equally upsetting and equally likely to cause anosognosia. In fact, because most people are right-handed, weakness on the right side might be even more upsetting and therefore *more* likely to result in psychologically motivated denial.

Additional evidence against the ego defense mechanism hypothesis comes from research showing that anosognosia can occur even when there is no threat of permanent paralysis. In a procedure pioneered by June Wada (Strauss & Wada, 1983), patients being evaluated for possible brain surgery had an anesthetic injected into one side of their brain at a time (Adair et al., 1995; Gilmore et al., 1992). This *Wada test* temporarily "turns off" either the left hemisphere or the right hemisphere without causing permanent brain damage. When the right hemisphere was "turned off" in this way, participants became paralyzed on the left side of their bodies. When they were asked about their experience, they recalled most details correctly, but most of them showed anosognosia—that is, they said that they did not notice any weakness or paralysis. When the left hemisphere was anesthetized, though, patients not only became weak on the right side but also later reported awareness of the paralysis. These data are hard to explain as being due to ego defense mechanisms because once participants had recovered from their left-side paralysis, why would they be motivated to deny that it had occurred?

Are there alternative ways of interpreting the evidence?

One problem with the Wada test is that it is difficult to compare the experiences that patients have during left- versus right-hemisphere anesthesia. The problem is that because speech areas are on the left side, people are usually unable to speak when their left hemisphere is "turned off." This doesn't happen on the right side, so the only way to do a direct comparison of the experience of left- versus right-hemisphere inactivation is to ask the patient questions after the anesthetic has worn off. If it were possible to talk to people during the left-hemisphere inactivation, perhaps they would show anosognosia because at that particular moment, there could be enough distress to motivate denial.

This interpretation is supported by research from decades ago with patients who had suffered a stroke causing hemiparesis (Weinstein & Kahn, 1955). When these patients' families were interviewed, it turned out that those patients who, before their stroke, had tended to cope with stress through denial were the ones most likely to deny their hemiparesis. Patients who did not show anosognosia were described by their families as less likely to have previously used denial as a coping strategy. These data suggest that denial of hemiparesis could be an exaggeration of a person's typical stress-coping tendencies.

What additional evidence would help evaluate the alternatives?

The results of this and other family report studies might be affected by *retrospective bias*. That is, once they know that their relative is denying hemiparesis, family members might be more likely to recall similar episodes of denial in the relative's past and to forget about episodes in which the patient had coped with stress in other ways. Similarly, if a relative isn't denying the symptoms caused by a stroke, perhaps family members will be less likely to recall incidents in which the patient did use denial in stressful situations.

One way around the problem of retrospective bias would be to do a *prospective* study in which a large group of individuals is identified, their typical stress-coping tendencies are assessed, and then they are contacted on a regular basis for many years. The ego defense mechanism hypothesis would be supported in such a study if the people in the group who were most likely to use denial as a coping mechanism are also the ones most likely to display anosognosia following a stroke.

What conclusions are most reasonable?

It is probably true that some individuals who suffer neurological deficits may use denial or other psychological defense mechanisms to avoid facing their distressing problems, but given the neurological evidence we have reviewed, it seems reasonable to conclude that most cases of anosognosia reflect a true lack of awareness of neurological deficit.

Perceptual Disturbances

As described in the chapter on perception, the brain must organize, recognize, and interpret the information we receive from our eyes, ears, and other senses if we are to make sense of the world. These vital perceptual functions depend on the normal operation of specific regions of the brain. For example, visual information from the eyes goes to the thalamus and then to particular areas in the occipital lobe of the cerebral cortex, where the information is analyzed further. From there, visual information is sent along two pathways. Along each of these pathways are a series of connected cortical regions that perform specialized analyses that allow us to experience different aspects of visual perception (Ungerleider & Mishkin, 1982; see Figure 20.7). The pathway leading toward the ventrolateral temporal lobe (on the sides of the head—"ventral" means toward the bottom part of the brain, and "lateral" means toward the outside of the brain) has been called the "what" system because the cortical regions

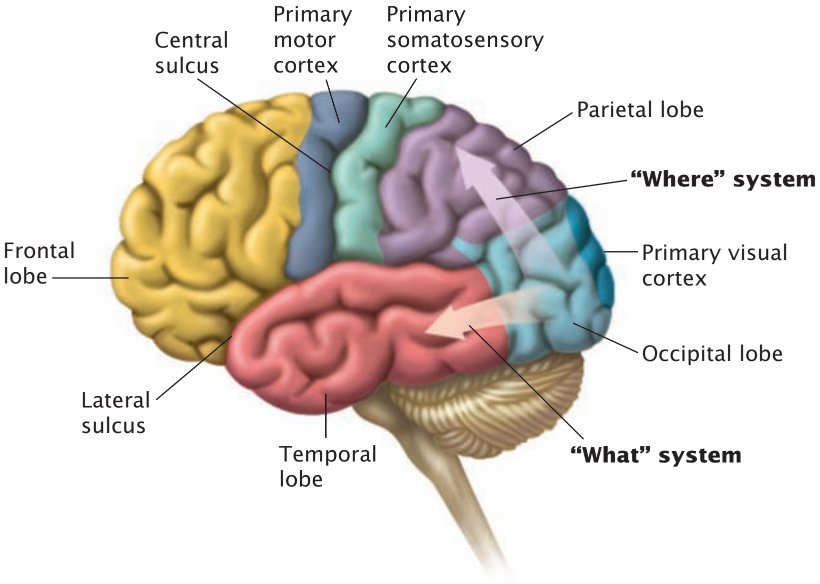


FIGURE 20.7
"What" Versus "Where" Visual Pathways
Research suggests that visual information reaching the primary visual cortex is sent along two separate but parallel systems. The "where" system focuses on an object's location in space and how it is moving. The "what" system determines the identity of the object.

along this pathway help us decide what we are seeing—a dog or a car, for example. The pathway leading toward the parietal lobe (near the top of the head) has been called the "where" system because it processes information about the location of objects and where those objects are in relation to one another. This system helps us understand, for example, that the dog is sitting in the car. Damage to our perceptual systems can result in **perceptual disturbances**.

For example, damage to the "what" pathway causes a condition called *visual agnosia* (Bauer & Demery, 2003). As in the case of Max, individuals with visual agnosia can see objects in the world, describe them, and even draw them, but they cannot identify them on the basis of their appearance (Rubens & Benson, 1971). So a visual agnosia patient can correctly define the word *apple* and, based on how it feels, correctly state that the neurologist has placed an apple in the person's hand. In other words, these patients still know what apples and other objects are, but they have lost the ability to link visual images of these objects to the part of the brain where that knowledge is stored.

Visual agnosia may leave some patients unable to name anything they see. For others, the problem occurs only when they try to name certain categories of objects (Bauer & Demery, 2003). For example, some people appear to have visual agnosia only for manufactured objects, such cars, books, or drinking glasses, but can still correctly identify on sight a tree, a dog, or any other living thing (Riddoch et al., 2008). In other cases, only manufactured objects can be named on sight (Riddoch et al., 2008; Thomas & Forde, 2006). These case observations suggest that information about natural versus manufactured objects must be processed in different ways by different brain areas. Visual agnosias can be even more specific. For example, there appears to be a brain system that is specialized for visual recognition of faces (Farah, 1996). When this aspect of the "what" system is damaged, the result is *prosopagnosia* (pronounced "proh-suh-pag-NOH-zhuh"), a condition in which a person can no longer recognize faces, even very familiar ones, including the patient's own face in a photograph or mirror (Barton et al., 2004; Bentin et al., 2007; Stephan & Caine, 2009). The facial recognition system appears to depend on temporal lobe structures; most people who develop prosopagnosia have damage to these areas on both sides of the brain (Ettlin et al., 1992), but sometimes a lesion on the right side alone is enough to produce a facial recognition syndrome (Barton et al., 2002).

In a different kind of face-related perceptual disturbance, people can still recognize faces, but they believe that a parent, a spouse, or some other familiar person has been replaced by an "imposter." This false belief, known as *Capgras syndrome* or *Capgras delusion* (pronounced "KAHP-grah") in recognition of the French psychiatrist who first reported it (Capgras & Reboul-Lachaux, 1923), tends to occur after temporal lobe damage. The damage appears to create a disconnection between brain areas that recognize faces from those that allow us to have a sense of familiarity (Ramachandran, 1998). Capgras delusions are usually permanent, though there is at least one case in which the condition was cured by antiseizure medication (Shenker, 2010).

What happens after damage to the "where" system? As you might expect, this kind of damage creates problems in the visual perception of objects in space and how they are related to one another. A particularly interesting example is called *simultanagnosia* (pronounced "sih-MUL-tun-ag-NOH-zhuh") (Wolpert, 1924), a condition in which a person can see parts of a visual scene but has difficulty perceiving the whole scene. In a sense, a person with simultanagnosia can see the "trees" but cannot see the "forest." So if simultanagnosia patients were to look at the pattern shown in Figure 20.8, they could see all the "Ts" but not the larger letter "H" formed by the smaller letters.

One patient described her perceptions as follows (Shenker, 2005):

Examiner: What do you see?

Patient: I see T, T, T, T, . . . Do I keep going?

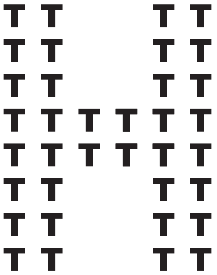

FIGURE 20.8

A "Global-Local" Stimulus

TRY THIS People with simultanagnosia have difficulty seeing an H in this stimulus but see the Ts easily. Try showing this pattern to several friends. Unless any of them have a similar neuropsychological disorder, you should be able to confirm that they will report seeing both the little Ts and the larger letter H.

perceptual disturbances
Neuropsychological disorders in which there are impairments in the ability to organize, recognize, interpret, and make sense of incoming sensory information.

Examiner: Anything else?

Patient: T, T, T, T, . . . lots of Ts.

Examiner: Are there any other letters?

Patient: No.

Examiner: Is there an H?

Patient: No, just Ts.

Examiner: Is there a big letter?

Patient: No, I don't see one.

Examiner: Is there a big letter H?

Patient: No.

Examiner: Do the little letters together form the shape of a big letter H?

Patient: I don't see how.

Examiner: (*outlines the H with finger*) Do you see how this is a big H?

Patient: I don't see an H.

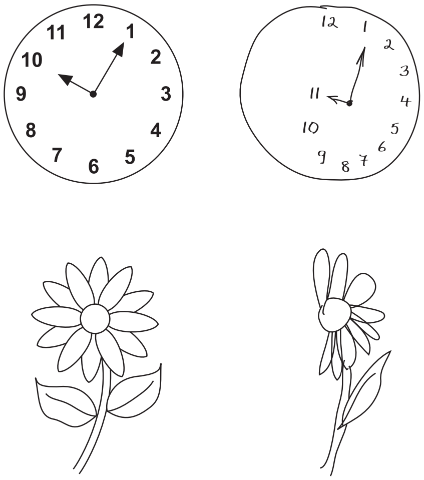

FIGURE 20.9
Examples of Hemineglect on a Drawing Test
When shown an object and asked to draw it, patients with hemineglect leave out details from one side of the object.

Simultanagnosia has been associated with damage or dysfunction on both sides of the brain, in the upper part of the parietal lobes (Coslett & Lie, 2008a, 2008b). Damage to the "where" system in a different region of the parietal lobes can cause *hemineglect* (Heilman, Valenstein, & Watson, 2000). This condition often occurs after a cerebrovascular accident and involves difficulty in seeing, responding to, or acting on information coming from either the right or, more often, the left side of the world (Heilman, Watson, & Valenstein, 2003). The side of space that is neglected is usually opposite the side where the parietal lobe lesion is located. A person with hemineglect will ignore food on one side of a dinner plate, fail to put makeup on one side of the face, and pay no attention to voices coming from one side of the room. As shown in Figure 20.9, when asked to draw a picture of, say, a flower or a clock, only half a drawing will be completed—the half on the side of space to which the person is still paying attention.

A fascinating aspect of hemineglect is that it is cannot be explained as being due to a lack of sensation from one side or the other. For patients with left hemineglect, it is as if the concept of "leftness" is lost, and so the left side of things is simply ignored (Bisiach, Capitani, & Tansini, 1979). This ignoring process is easy to demonstrate in some patients. The neuropsychologist simply holds up one hand on each side of the patient's visual field and then asks the patient to say when any fingers are wiggling. In many cases of hemineglect, patients may be able to correctly report when fingers are wiggling on the right *or* on the left, as long as the wiggling is only on one side at a time. When there is wiggling on both sides, though, these patients may report seeing it only on the side to which they pay attention. These cases demonstrate that some hemineglect patients are capable of seeing both sides of space; they don't have a pure sensory problem. They are simply more likely to pay attention to one side of the world and to ignore the other. The tendency to do so can be reduced, though. In one study, patients showed increased awareness of the normally neglected side of space while listening to music that put them in a more positive emotional state (Soto et al., 2009).

Some patients with hemineglect also have sensory problems. They may be blind in their left visual field, for example. It may seem surprising, but neuropsychologists can show that even in these patients, the tendency to ignore one side of space cannot be explained by their sensory loss. For example, patients with left hemineglect may not respond to the sound of a voice coming from the left. Is it because of a problem in their left ear? No, because the sound was heard by their right ear too. Also, left hemineglect patients may ignore the left side of an object even if the entire object appears in their right visual field.

FOCUS ON RESEARCH METHODS

Studying Hemineglect

Showing that hemineglect is not explained by sensory problems alone can be tricky. After all, in many cases of hemineglect, the brain damage that caused it also caused a loss of sensation from the same side. Also, most tests for hemineglect rely on giving a person some kind of sensory information to respond to. How can one show that hemineglect is not due to a sensory problem if you can only test for it by having people respond to the sensations they receive?

What was the researcher's question?

Edoardo Bisiach (Bisiach, Luzzatti, & Perani, 1979) reasoned that if hemineglect was truly a problem with understanding that a particular side of space exists, then this problem should persist even for a scene that is not viewed directly but is instead put together using only one's imagination.

How did the researcher answer the question?

Bisiach tested patients who had right hemisphere lesions and left-sided hemineglect. He created randomly shaped stimuli that looked a bit like clouds. The stimuli were passed behind a vertical slit so that as the image moved across, patients could see only a small "slice" of it at a time (see Figure 20.10). In other words, the only way to see the whole stimulus was to imagine all the "slices" assembled in the mind's eye. Patients were shown two of these passing images at a time, one passing by the top part of the slit and the other passing by the bottom part of the slit. On some trials, the two stimuli were identical; on other trials, only their left sides were different; and on still others, only their right sides were different. The patients' task was to decide if the two stimuli were the same or different.

What did the researcher find?

Patients with left-sided hemineglect were able to determine when the stimuli were different if the right sides were different. But these patients could not detect differences between the stimuli if the left sides were different.

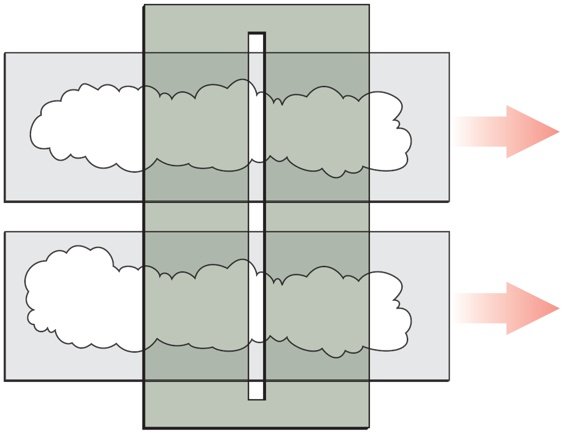
What do the results mean?

Because of the slit, the patients could not see the left and right sides of the images at the same time. This means that their failure to notice differences on only the left side did not reflect an inability to see the left side of space. Instead, these results suggest that hemineglect occurs when patients ignore stimulation that is on a particular side of space, even when they are assembling that stimulation through memory and imagination.

FIGURE 20.10

Studying Hemineglect

Here are examples of the random cloudlike shapes used by Bisiach, Luzzatti, and Perani (1979) to explore whether hemineglect is a sensory problem. Hemineglect patients could see only vertical "slices" of these shapes as the patterns passed behind a narrow vertical slit. So to see these shapes as whole patterns and to decide whether pairs of patterns were the same or different, the patients had to build an image of each pattern in their minds.



What do we still need to know?

Different kinds of hemineglect are produced by damage in different parts of the brain (Watson & Heilman, 1979). So it is not clear if Bisiach's patients, who had damage in their parietal lobes, are representative of all hemineglect patients. Notice, too, that the stimuli in Bisiach's study were all visual. Would the same results appear in research using imagined touches or sounds, for example? These are questions to be answered by further research on the fascinating topic of hemineglect.

LINKAGES

LINKAGES How does damage to language areas of the brain affect language abilities? (a link to Biological Aspects of Psychology, p. 90)

Language Disorders and the Brain

When people suffer disruptions in the functioning of brain regions that normally support their ability to speak, read, write, and understand language, specific aspects of these language skills will fail, resulting in corresponding disorders in the person's language abilities. The precise nature of these **language disorders**, also called **aphasias** (pronounced "uh-FAY-zhuhz"), can be identified using detailed neuropsychological testing. In this section, we discuss several subtypes of aphasias (Caplan, 2003a), each of which is associated with damage or dysfunction in a particular area of the brain's language centers.

Most aphasias occur as a result of damage to the left side of the brain, often from stroke or trauma but sometimes from a neurodegenerative disease process called *frontotemporal degeneration* (*FTD*) (Boxer & Miller, 2005; Rabinovici & Miller, 2010). FTD gradually kills nerve cells in the front section of the brain's temporal or frontal lobes, often on one side more than on the other (Neary, Snowden, & Mann, 1993; Yamamoto et al., 2009; see Figure 20.11). The result is similar to a stroke in the sense that FTD tends to affect a fairly specific brain area, but unlike the sudden symptoms of a stroke, FTD symptoms develop gradually over a period of years. If FTD is focused on the brain's language-related regions, the result is a condition called *primary progressive aphasia* (Grossman & Ash, 2004; Rogalski & Edmonds, 2008). Let's consider where these language-related brain regions are, what they normally do, and what else can happen when their functioning is disrupted.

FIGURE 20.11
Frontotemporal Degeneration
In frontotemporal degeneration, a relatively limited part of the brain can become extremely shrunken, as shown here.

As described in the chapter on biological aspects of psychology, the brain has several language areas. These interconnected regions work together as a network, and all of them must work properly in order for us to use and understand language. For example, it appears that *Broca's area* is vital to our ability to translate thoughts into words or writing that will be clear and meaningful to others. People who suffer damage to Broca's area (see Figure 20.12) display **Broca's aphasia**, which is manifested mainly in the loss of language fluency (Keller et al., 2009). That is, people with Broca's aphasia are no longer able to express themselves smoothly and easily (Kertesz, 1993). Instead, they speak in a halting, sputtering manner, with great effort and often with much frustration. There may be other symptoms as well, including a change in the kinds of words that individuals produce (Benson & Geschwind, 1971). Most of the words that patients with Broca's aphasia can still speak or write are those that refer to concrete objects, such as *book* or *pillow* or *water*, rather than those that refer to abstract ideas such as *justice* or *literature* or *weather*. These patients also tend to use mainly concrete nouns and verbs, leaving out the more abstract articles, adjectives, and adverbs they once spoke or wrote. This change in word usage results in a "telegraphic" speaking style that recalls a bygone era when people sending telegrams had to pay for each word in a message. A Broca's aphasia patient who once would have said, "Please give me the spoon," might now say simply, "Give spoon." Sometimes Broca's aphasic patients make mistakes when naming objects. Such naming errors are called *paraphasias*, and in Broca's aphasia, they tend to be *phonemic paraphasias*, or errors in the way a word should sound. So a person with Broca's aphasia might look at a pen and call it a "peb." Finally, people with Broca's aphasia may have some subtle problems in understanding grammar or other aspects of language (Cannizzaro, 2009; Caplan, 2003a, 2003b). In one such problem, called *agrammatism*, they may not understand that the sentences *The boy hit the girl* and *The girl was hit by the boy* express the same meaning

language disorders (aphasias) Neuropsychological disorders in which there are disruptions in the ability to speak, read, write, and understand language.

Broca's aphasia A language disorder in which there is a loss of fluent speech.

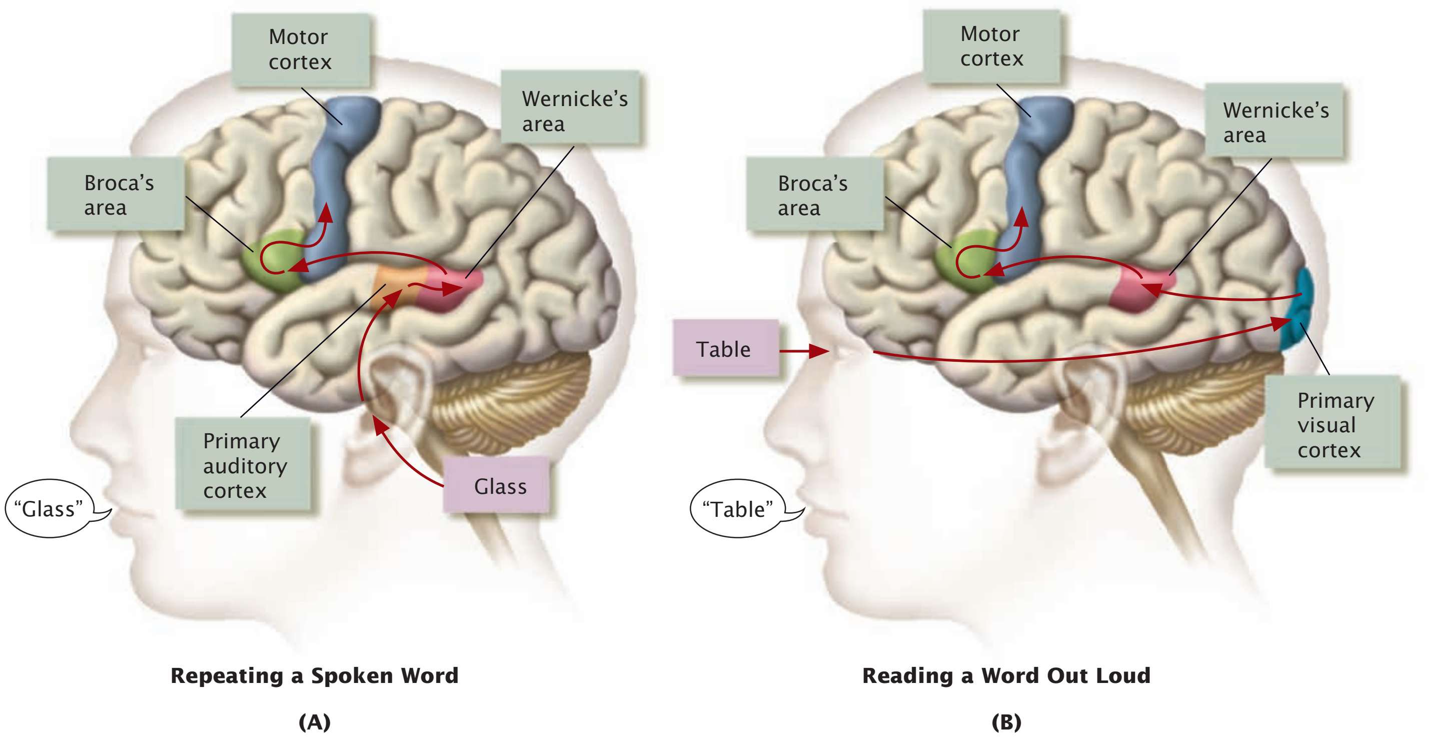

FIGURE 20.12

The Wernicke-Geschwind Model of Aphasia

The Wernicke-Geschwind model of aphasia accounts for many, but not all, of the findings associated with the major aphasias. The pathways shown in part A transmit information when a participant is instructed to repeat a spoken word. The image shown in part B traces the flow of information when the person is asked to read a written word out loud.

People with aphasia caused by damage to *Wernicke's area* (see Figure 20.12) have a different pattern of problems (Goodglass & Kaplan, 1982). This area is involved in the ability to extract the meaning of language-related sensory information, so if its functioning is disrupted, people have difficulty understanding what they read or what others say (Kertesz, 1993). In fact, because everything everyone says sounds like nonsense to a person with **Wernicke's aphasia**, the world must seem like a suddenly strange and even unfriendly place where everyone *else* has a problem. Further, although people with Wernicke's aphasia still speak fluently and effortlessly, what they say is far from normal. Most notably, they make *semantic paraphasias,* that is, naming errors in which they use words that have the wrong meaning. So when trying to name a pen, they may call it a "book." In contrast to Broca's aphasia, people with Wernicke's aphasia tend to use lots of adverbs, adjectives, and articles but relatively few nouns and verbs. So the speech of a patient with Wernicke's aphasia may be incomprehensible. For example, when attempting to describe a picture of a woman and her children in the kitchen, a Wernicke's aphasia patient may say, "Over here is the top of the rest for the other rapid sheesh of many red sitters." This kind of output, combined with naming errors, can make the speech of a person with Wernicke's aphasia sound so disorganized that it may be mistaken for the "word salad" produced by some people with severe schizophrenia (Sambunaris & Hyde, 1994; see the chapter on psychological disorders). Yet because they do not recognize all the mistakes they are making or appreciate the oddness of their speech, people with Wernicke's aphasia are often puzzled and upset when others do not seem to understand them or respond as expected.

Damage in the brain's left hemisphere is associated with most language disorders, but communication problems can also occur after right-hemisphere damage. In general, people with right-hemisphere damage can still speak words well and can understand the words that they hear and see fairly well. However, they no longer use tone of voice properly when they speak, or they may no longer use other people's tone of voice to help them understand what those people mean (Ross & Monnot, 2008). This problem, called *aprosodia* (pronounced "ap-ruh-SOH-dee-uh"), can take several forms (Ross, 1981, 2006). For example, damage to the right frontal lobe can cause *expressive aprosodia,* in which people speak in such a dull monotone that it may be necessary for them to say something like "I am angry" in order to convey their emotional tone.

Wernicke's aphasia A language disorder in which there is a loss of ability to understand written or spoken language and to produce sensible speech.

However, these patients may still be able to correctly understand and use cues from other people's tone of voice. By contrast, people with damage to the right temporal and parietal regions may have a *receptive aprosodia,* which means that they can use tone of voice correctly when they speak but have difficulty understanding the meaning of other people's tone of voice. So if someone were to sarcastically say, "Well, that was really smart," meaning just the opposite, a person with receptive aprosodia may miss the sarcasm, pay attention only to the words themselves, and say, "Thanks!"

Movement Disorders

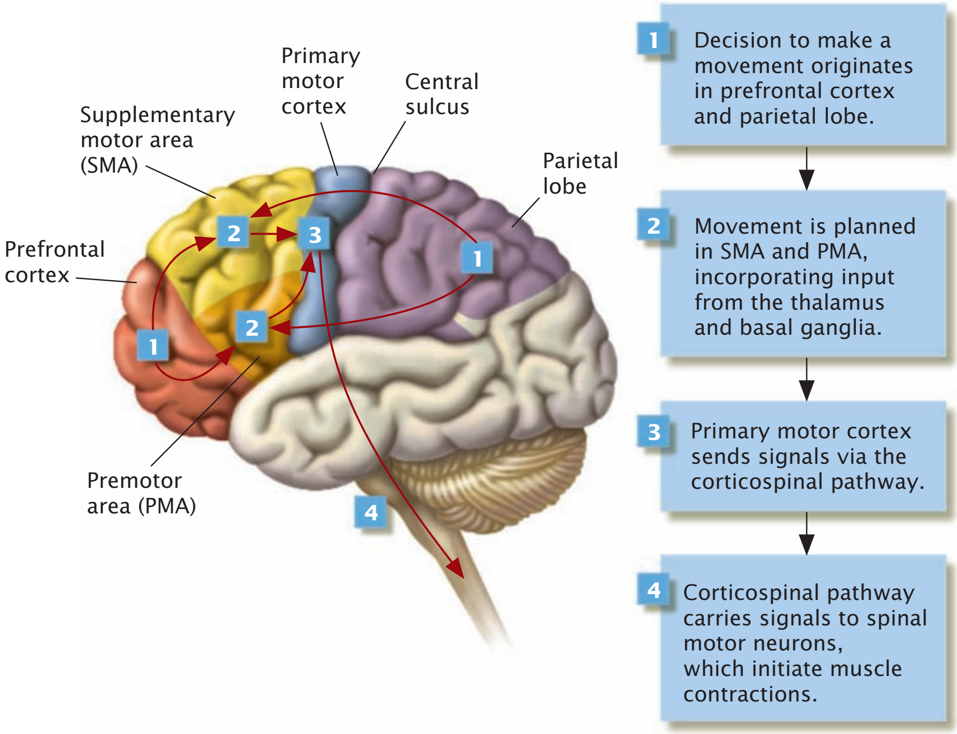
The brain's motor pathways are "wired" to our muscles in ways that allow us to move our limbs and body, but the knowledge of how to move in order to effectively accomplish our goals is not built in to that system. Using silverware, pedaling a bicycle, sucking on a straw, or swinging a hammer are just a few examples of the many coordinated movements that each of us learn from experience. A network of special brain systems control such learned motor skills by instructing the brain's motor control centers to make the movements needed for each action sequence (Krakauer & Shadmehr, 2007; see Figure 20.13). These brain areas tell the motor system what combinations of movements to make for a specific kind of task. If a part of this special network is damaged, the result is a form of **apraxia** (pronounced "uh-PRAK-see-uh"), or **movement disorder**, in which learned motor skills are disrupted (McClain & Foundas, 2004).

There are two main types of apraxia (Heilman & Gonzalez-Rothi, 2003; Pearce, 2009). In *ideational apraxia,* the individual movements needed to perform a task are correctly executed but in the wrong order. So although a person with ideational apraxia can still open a tube of toothpaste, wet her toothbrush, squeeze paste onto the brush, insert the brush in her mouth, and do a good job of brushing, she might begin to brush before putting toothpaste on her brush, or she might squeeze the toothpaste tube first and then unscrew the cap.

A more common problem is *ideomotor apraxia,* which involves difficulties not in the sequence of skilled movements but in performing them (Wheaton & Hallett, 2007). So a person with ideomotor apraxia will try to execute each step in toothbrushing in

movement disorder (apraxia)
Neuropsychological disorders in which there are impairments in the ability to perform or coordinate previously normal motor skills.

FIGURE 20.13
The Initiation of Voluntary Movement
A network of brain regions is involved in initiating voluntary movements.



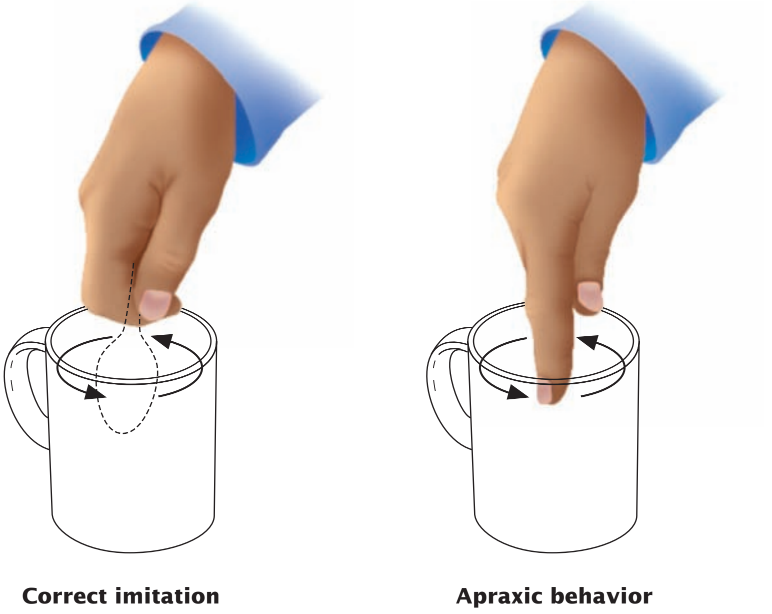
1 Decision to make a movement originates in prefrontal cortex and parietal lobe.

2 Movement is planned in SMA and PMA, incorporating input from the thalamus and basal ganglia.

3 Primary motor cortex sends signals via the corticospinal pathway.

4 Corticospinal pathway carries signals to spinal motor neurons, which initiate muscle contractions.

FIGURE 20.14
An Example of Apraxic Motor Behavior
When imitating the movements involved in using a common object, individuals with apraxia may mistakenly use an arm or a leg to represent that object. So instead of showing how they would move in order to use a tool, they act as if their limb is the tool itself.



its proper order but may have difficulty in positioning her hand to hold the brush and may be unable to time the sequence of arm and hand motions required to actually brush her teeth. In one kind of ideomotor apraxia, the person may use a finger or other body part as if it were a tool, perhaps brushing with the finger or using it to try to turn a screw. In such cases, the person cannot seem to figure out how to use the brush or screwdriver or other tool they once used with skillful ease (see Figure 20.14).

Dementia

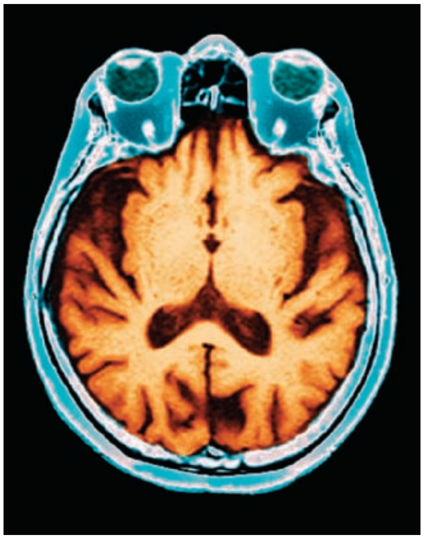
We have already seen that in cases of delirium, people show reduced or heightened levels of consciousness, and many psychological abilities may fail at once. But these deficits are usually reversible, such that when the toxin or other cause of delirium disappears, the deficits do too. In conditions known as *dementia,* however, there is usually no waxing and waning of consciousness; wakefulness and alertness remain mostly normal, but many other mental functions are impaired (Knopman & Selnes, 2003; Manning, 2004). Specifically, in **dementia**, memory declines from its previous level, and there is also impairment in some other area of psychological functioning such as perceptual ability, language, or learned motor skills. In addition, to be diagnosed as dementia, the impairments must be significant enough to cause problems in the person's ability to function at work, in social situations, or in everyday tasks such as driving, cooking, or balancing a checkbook. In most cases, but not all, dementia is gradual, progressive, and irreversible. It has been estimated that about 34.4 million people worldwide have dementia (Wimo, Winblad, & Jönsson, 2010).

A condition known as *mild cognitive impairment* (*MCI*) may precede the appearance of some kinds of dementia (Dubois, 2004; Petersen & Morris, 2005). In *amnestic MCI,* for example, a person begins to have memory problems that are reflected in well-below-average scores on neuropsychological tests. There are no other deficits, though, and the person may have adapted well enough to the memory loss that there is no significant disruption in daily functioning. People with amnestic MCI may get worse, however, and about 2 to 10 percent of them each year progress to the point that they are considered to have dementia (Mitchell & Shiri-Feshki, 2009). Identifying people when they are still in this relatively early stage of memory loss is important partly because medication is available that might stabilize memory and delay the development of full-fledged dementia (Petersen et al., 2005; Tabert et al., 2006).

Dementia is often caused by a progressive neurodegenerative disease, and the most common of these, accounting for 60 to 80 percent of all cases, is Alzheimer's disease

dementia Neuropsychological disorders in which there are significant and disruptive impairments in memory, as well as in perceptual ability, language, or learned motor skills.

(Alzheimer's Association, 2009; Fratiglioni & Qiu, 2009). About 5.3 million people have Alzheimer's disease in the United States alone, where its economic costs are set at more than $148 billion a year and where its costs in personal suffering are incalculable (Alzheimer's Association, 2009). The percentage of people with Alzheimer's disease doubles after about every five years after the age of 60. As a result, about 13 percent of people over age 65 have this disease, and the chances of developing Alzheimer's disease increase dramatically after age 75 and again after 85 (Alzheimer's Association, 2009). With more people than ever living longer and longer lives, current estimates suggest that by the year 2050, Alzheimer's disease will affect as many as 16 million people in the United States (Alzheimer's Association, 2009).



© Zephyr/Photo Researchers, Inc.

FIGURE 20.15

Brain Atrophy in Alzheimer's Disease

Alzheimer's disease causes some brain cells to stop working and eventually die, while other brain cells may be unaffected. Where brain cells die off, the cortex shrinks, leaving gaping spaces.

Alzheimer's disease was first described in 1907 by the German neurologist Alois Alzheimer (Devi & Quitschke, 1999). He told of a 46-year-old woman identified as "Auguste D.," who had developed what Alzheimer described as an "early onset senility" (see Figure 20.15). When she died a few years later, he examined her brain and found two types of microscopic abnormalities. The first appeared as *neurofibrillary tangles,* which are dead and dying nerve cells that have become twisted and misshapen. The second abnormality was clumps of protein deposits, called *amyloid plaque,* lying around the outside of the dead and dying nerve cells. To this day, the ultimate diagnosis of Alzheimer's disease depends on the appearance of these tangles and plaque deposits (Graeber & Mehraein, 1999; Wengenack et al., 2008).

Today we know that the brain areas where neurofibrillary tangles are most numerous in Alzheimer patients are precisely the areas that fail to work properly and cause most of these patients' symptoms. As for amyloid plaque, scientists believe that it plays a key role in causing at least some forms of Alzheimer's disease. We all develop some of this plaque as we get older, but although it is toxic to nerve cells, it usually causes no more harm than other signs of aging, such as hair loss or wrinkles. However, in Alzheimer's disease patients, amyloid plaque is much more abundant than normal, and according to some researchers, this excessive amount of plaque causes the brain damage that results in Alzheimer's symptoms (Hardy, 2006; Swerdlow & Khan, 2009).

Studying the brains of deceased Alzheimer's patients has shown that the disease mainly damages neurons that use the neurotransmitter *acetylcholine* (Perry, 1980), especially those in the parietal and medial temporal lobes on both sides of the brain (Cummings, 2004; Knopman & Selnes, 2003). Because the parietal lobes are important for locating objects in space, Alzheimer's disease patients have difficulty drawing some kinds of shapes and may easily get lost as they drive or walk around. Many Alzheimer's patients are endangered every day by wandering away from home or from the care facility in which they live (Rolland et al., 2007). Because the left parietal lobe contains brain areas important for language, patients with Alzheimer's disease may also develop *anomia,* a condition in which it becomes hard to name objects even if they know what the objects are. The left parietal lobe usually also contains brain areas that are important in performing learned motor skills such as using a hammer or a spoon, so Alzheimer's patients commonly develop apraxia. And because the medial temporal lobes contain the hippocampus, these patients experience impairment in the ability to form new memories. Old memories, the ones already formed and stored elsewhere, usually remain accessible until the disease has progressed to its later stages. So as in the case of H.M., Alzheimer's disease patients may remember details from their early adulthood but not a conversation from yesterday. Finally, because the temporal lobes are also important for the ability to interpret visual sensations, patients with Alzheimer's disease sometimes develop visual agnosia and so may not recognize the objects they see.

In another kind of dementia, called **vascular dementia**, memory loss and other psychological deficits are caused by restrictions in the supply of blood to the brain (Kirschner, 2009; Topakian & Aichner, 2008). We have already mentioned that when a blood vessel in the brain is blocked, the brain cells die in the tissue that normally receives oxygen and nutrients from that blood vessel. Sometimes this loss of blood supply occurs in very tiny blood vessels, resulting in the death of only a tiny amount of

vascular dementia A form of dementia caused by multiple restrictions of the brain's blood supply.

brain tissue. Such injuries may not cause symptoms when they first occur, especially if vital areas are not affected, but if many small injuries occur repeatedly, more and more brain tissue is lost (Hallam et al., 2008), and the cumulative effect can be an impairment of memory and other psychological functions (Fisher, 1989).

Vascular dementia accounts for about 17 percent of the dementia seen in people over the age of 70, making it second only to Alzheimer's disease as a common cause of dementia (Alzheimer's Association, 2009). The two conditions may occur in the same individual (Topakian & Aichner, 2008), but the symptoms of vascular dementia often differ from those of Alzheimer's disease (Knopman, 2006). Vascular dementia patients show memory loss, including the forgetting of recent events, but in contrast to Alzheimer's disease, the hippocampus is usually relatively well preserved. So vascular dementia patients should still be able to form new memories. Why, then, do these people have difficulty remembering new material? In some cases, the answer may be that they have more of a problem in retrieving recent memories than in forming them. This subtle difference highlights the importance of careful neuropsychological assessment. Differences between vascular dementia and other impairments have also been found on behavioral tests (Milan et al., 2008), as well as in the appearance of deficits such as aphasia, apraxia, and dyslexia in vascular dementia patients (Topakian & Aichner, 2008).

A proper testing protocol can help establish the likely cause of a dementia. This information is useful because new medications are becoming available that can stop or slow the progression of certain dementias (Caccamo, Fisher, & LaFerla, 2009; Cummings, 2004). It is important for physicians to know exactly what form of dementia they are dealing with in each case so that they can prescribe the correct medication and help families plan for the future problems that dementia is likely to bring (Leifer, 2009). Drugs such as dimebolin (Dimebon), galantamine (Reminyl), and rivastigmine (Exelon) have been shown to be somewhat effective at slowing the progress of Alzheimer's disease and are well tolerated by patients (Burns et al., 2009; Doody et al., 2008; Small & Dubois, 2007). Certain antidepressant medications may have similar benefits (Hashioka et al., 2009), and antipsychotic drugs such as risperidone have shown potential for treating some of the behavioral and psychological symptoms of Alzheimer's disease (Oshima, 2008).

Choosing the right drug at the right time can help patients enjoy a better quality of life for a longer time and can delay for years the need for nursing home care (Geldmacher et al., 2003). Accordingly, it would be ideal if Alzheimer's disease and other dementias could be diagnosed even before their symptoms appear. Scientists are working to develop such early diagnostic tests based on molecular and brain imaging (Drzezga, 2008; Hallam et al., 2008; Nordberg, 2008; Wengenack et al., 2008), analysis of EEG brain waves (Gasser et al., 2008), refined neuropsychological assessment batteries (De Santi et al., 2008), and observation of various behavioral changes (Caputo et al., 2008). One study found, for example, that patients who displayed three or more subtle neurological abnormalities, such as difficulty with balance, were more likely than others to show cognitive decline over the next eight years (Inzitari et al., 2008). Another found that the inability to smell certain types of odors may be an early sign of Alzheimer's disease or dementia related to frontotemporal degeneration (FTD), and a third found that losing the ability to appreciate sarcasm may signal the presence of FTD (Kipps et al., 2009; McLaughlin & Westervelt, 2008).

Giving the right prescription at the right time is of little use, though, if, as often happens in cases of dementia, the patients forget—or are unable or unwilling—to take their medication on the proper schedule. To address this compliance problem, pharmaceutical companies have begun to offer some of their dementia medications in transdermal patches. When applied to the skin these patches automatically provide the correct daily drug dose (Small & Dubois, 2007).

Progress in the development of new medications and early diagnostic tests leads many researchers to hope that instead of just stopping or slowing the progress of dementia, it may someday be possible to reverse its course, allowing some patients to once again enjoy more normal cognitive functioning (Lacor, 2007). And as discussed in the human development chapter, the appearance of dementia may be delayed or prevented in those who spend their lives engaged in stimulating mental activity, interactions with friends, and healthy eating and exercise (Fratiglioni & Qiu, 2009). ("In Review: Major Neuropsychological Disorders" summarizes the various dysfunctions discussed here.)

IN REVIEW Major Neuropsychological Disorders

Syndrome	Type of Difficulty	Areas of Brain Malfunction
Apraxia	Making learned skilled movements even if not weak or confused	Usually left cerebral hemisphere parietal or frontal lobes
Visual agnosia	Attaching meaning to visual sensations	Temporal lobes, often bilateral
Anosognosia	Becoming aware of the loss of neurological function	Usually right cerebral hemisphere
Hemineglect	Paying attention to one side of space	Usually right parietal lobe
Aphasia	Using language as a communication system	Usually left cerebral hemisphere
Aprosodia	Using tone of voice as a communication tool	Usually right cerebral hemisphere
Dementia	Memory and at least one other psychological ability that are severe enough to impair functioning	Variable, depending on the cause of the dementia

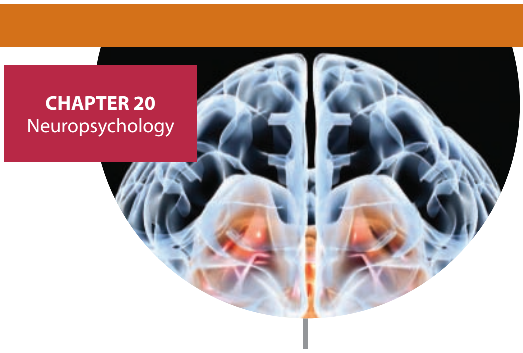
1. A patient who has become forgetful but has no problems in other areas of cognitive function may be said to have ____________.

2. A dementia patient whose hippocampus is relatively intact and can still form new memories probably has ____________ dementia.

3. A patient with thiamine deficiency who is forgetful but makes up memories and believes they are real probably has ____________.

LINKAGES

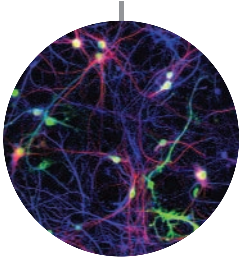
As noted in the introductory chapter, all of psychology's subfields are related to one another. Our discussion of language disorders illustrates just one way in which the topic of this chapter, neuropsychology, is linked to the subfield of biological psychology, which is described in the chapter on biological aspects of psychology. The Linkages diagram shows ties to two other subfields, and there are many more ties throughout the book. Looking for linkages among subfields will help you see how they all fit together and help you better appreciate the big picture that is psychology.



CHAPTER 20
Neuropsychology

LINKAGES

How does damage to language areas of the brain affect language abilities? *(ans. on p. 823)*



CHAPTER 3
Biological Aspects of Psychology

What disorders are caused by damage to brain areas involved in memory? *(ans. on p. 826)*

CHAPTER 7
Memory

What psychological tests are used in diagnosing neuropsychological disorders? *(ans. on p. 810)*

CHAPTER 10
Cognitive Abilities

SUMMARY

Neuropsychology is the subfield of psychology whose goal is to explore and understand the relationships among brain processes, human behavior, and psychological functioning.

Foundations of Neuropsychology

There are two main assumptions in neuropsychology. The first is that complicated mental tasks such as memory involve many subtasks that can be studied separately. The second is that different psychological processes are controlled by different brain regions or different combinations of brain regions. Experimental neuropsychologists use these assumptions as they conduct research on how the brain controls and organizes human mental activity. *Clinical neuropsychologists* use the results of neuropsychological research to try to understand the nature and location of brain disorders seen in individual patients.

A Brief History of Neuropsychology

Neuropsychology's early history focused on debates over *localization of function,* the idea that specific psychological functions are governed by specific parts of the brain. Early evidence for this notion was dismissed by serious scientists, but by the 1860s, localization of function began to be accepted, and it now forms the basis for much of what we know about neuropsychological functioning.

Modules and Networks

Recent theories of localization center on the idea that the brain is organized into *modules,* each of which performs its own unique analysis of information and works together with varying combinations of other modules throughout the brain to perform all aspects of behavior and mental processes.

Lesion Analysis

Experimental neuropsychologists today use *lesion* analysis to try to understand the complexities of localization of function; they look at how damage (lesions) in particular places in the brain relate to the appearance of particular problems.

Neuropsychological Assessment

Clinical neuropsychologists use a wide variety of *neuropsychological assessment* methods to help determine the nature of a patient's neuropsychological problems and even to suggest where in the brain the problem may lie. These tests may consist of a standardized group of instruments, such as the Halstead-Reitan Battery, or they may be an individualized combination of tests chosen by the neuropsychologist with a particular patient in mind. In most cases, a standard battery is followed by some additional individualized tests.

Training for Neuropsychology

To develop their skills, clinical neuropsychologists typically earn a Ph.D. in clinical psychology with a focus on neuropsychology and then complete a postdoctoral internship.

Mechanisms of Brain Dysfunction

Brain dysfunctions can be caused by a number of conditions.

Cerebrovascular Accidents

One of the main causes of brain damage and dysfunction is a *cerebrovascular accident* (*stroke*), which occurs when the blood supply to a part of the brain is blocked, causing the death of brain cells in that region and the loss of that brain region's ability to exercise its normal control over some aspect of behavior or mental processing. Strokes can be disabling and sometimes deadly.

Traumatic Brain Injury

Damage and dysfunction can also result from *traumatic brain injury* (*trauma*), a sudden impact on the brain caused by a blow to the head, sudden and violent head movements, or other events that literally shake the brain inside the skull. The amount of damage and dysfunction following such events depends mainly on the amount of force involved and the degree to which the impact is cushioned by the action of the *cerebrospinal fluid.*

Neurodegenerative Diseases

Neurodegeneration is the gradual process of damage to brain cells caused by *neurodegenerative diseases* such as Alzheimer's, Parkinson's, and Huntington's or by infections, nutritional deficiencies, or genetic abnormalities.

Neuropsychological Disorders

The *syndromes,* or patterns of symptoms, associated with stroke, trauma, and neurodegenerative diseases appear as several kinds of neuropsychological disorders.

Amnestic Disorders

The hallmark of *amnestic disorders* is some significant disruption or loss of memory, as seen in conditions such as *anterograde amnesia,* in which new memories do not form, and *Korsakoff's psychosis* (*Korsakoff's syndrome*), in which memory distortions and *confabulations* are caused by a lack of thiamine.

Consciousness Disturbances

In *consciousness disturbances,* a person's normal awareness of the world is impaired. These conditions can range from loss of consciousness, as in coma or persistent vegetative state (which may result from damage to the *reticular formation*), to *delirium,* in which the patient alternates between reduced and elevated degrees of consciousness. In cases of anosognosia, a person may be paralyzed on one side of the body but have no awareness of the problem.

Perceptual Disturbances

People who experience *perceptual disturbances* may become unable to understand what objects, or certain categories of objects, are by looking at them (visual agnosia), may be unable to recognize faces (prosopagnosia), or have difficulty assembling the specific parts of a visual scene into a coherent whole (simultanagnosia). Patients with a perceptual disorder called hemineglect ignore one half of the world.

Language Disorders and the Brain

Language disorders usually result from damage to language areas on the left side of the brain and take the form of *aphasias,* in which the ability to speak or understand language is disrupted. The many forms of aphasia include *Broca's aphasia,* in which people can no longer speak fluently, and *Wernicke's aphasia,* which makes it difficult for people to understand what they read or hear, and although they can speak fluently, their speech makes little or no sense. Damage in the right side of the brain can result in aprosodia, the loss of ability to use tone of voice to express one's meaning or to understand the meaning of other people's speech.

Movement Disorders

Movement disorders, also known as *apraxias,* involve the inability to perform various motor skills or the inability to perform those skills in the correct order.

Dementia

Patients with *dementia* suffer gradually more significant and, usually, irreversible, loss of many mental functions, including impairment of memory, perception, language, and motor skills. It is usually caused by progressive neurodegenerative disorders such as Alzheimer's disease, though in *vascular dementia,* the cause is restrictions of the brain's blood supply. A condition known as mild cognitive impairment may precede the appearance of some forms of dementia.

LINKAGES TO FURTHER LEARNING

Now that you have finished reading this chapter, how about exploring some of the topics and information that you found most interesting? Here are some places to start.

Books

Oliver Sacks, *The Man Who Mistook His Wife for a Hat* (Simon & Schuster, 1985). Beautifully written and easily read stories describing real patients with specific neuropsychological syndromes such as aphasia, agnosia, and amnesia.

Kenneth M. Heilman, *Matter of Mind* (Oxford University Press, 2002). A readable review of some of the scientific basis for clinical neuropsychology, with stories illustrating syndromes and good discussions of lesion analysis and modularity.

Aleksandr R. Luria, *Mind of a Mnemonist: A Little Book About a Vast Memory* (Basic Books, 1968). Detailed case study written by a storied neuropsychologist that describes a man whose memory was so effective that he could not forget anything he learned.

Thomas Debaggio, *Losing My Mind: An Intimate Look at Life with Alzheimer's* (Simon & Schuster, 2003). A professional writer's autobiographical account of what it is like to have Alzheimer's disease.

Konrad Maurer and Ulrike Maurer, *Alzheimer: The Life of a Physician and the Career of a Disease* (Columbia University Press, 2003). A fascinating account of the German neurologist and his careful study of the first Alzheimer's disease patient.

Jenni A. Ogden, *Fractured Minds: A Case-Study Approach to Clinical Neuropsychology* (Oxford University Press, 2004). Vivid accounts of patients with a wide variety of neuropsychological syndromes.

On the Internet

CourseMate Access an integrated eBook and chapter-specific learning tools including flashcards, quizzes, videos, and more. Go to CengageBrain.com.

CENGAGENOW Want to maximize the value of your online study time? Take this easy-to-use study system's diagnostic pre-test, and it will create a personalized study plan for you. By helping you identify the topics that you need to understand better and then directing you to valuable online resources, it can speed up your chapter review. CengageNOW even provides a post-test so you can confirm that you are ready for an exam. Go to CengageBrain.com.

TALKING POINTS

Here are a few talking points to help you summarize this chapter for family and friends without giving a lecture.

1. Neuropsychologists try to understand how normal and abnormal brain functioning affects our behavior and mental processes.
2. Clinical neuropsychologists test patients with neuropsychological disorders to figure out which psychological functions have been disrupted and which brain areas might be causing the problems.
3. Most neuropsychologists have a Ph.D. in clinical psychology, and all have additional specialized training.
4. Neuropsychology is based on the assumption that particular psychological functions are controlled by particular areas of the brain.
5. Neuropsychological disorders are disruptions in behavior or mental processes caused by strokes, head trauma, or disease.
6. Certain kinds of brain damage not only cause paralysis or other disruptions in functioning but also leave the person unaware of the problem.
7. It is important to diagnose Alzheimer's disease early, while medication might still be effective in slowing the cognitive deterioration (dementia) caused by this disease.

This page intentionally left blank

APPENDIX A

Answers to In Review Questions

The questions at the bottom of each chapter's In Review charts are listed here, followed in parentheses by the correct answers. The questions are grouped under each chapter's title and by the name and page number of the In Review chart in which they appear.

The answer key for the optional Industrial and Organizational Psychology and Neuropsychology chapters appears in blue.

Chapter 1 Introduction to the Science of Psychology

In Review: The Development of Psychology (p. 18)

1. Darwin's theory of evolution had an especially strong influence on __________ism and __________ism. (functionalism; behaviorism)
2. Which school of psychological thought was founded by a European medical doctor? __________ (Psychoanalysis)
3. In the history of psychology, __________ was the first school of thought to appear. (structuralism)

In Review: Approaches to Psychology (p. 24)

1. Teaching people to be less afraid of heights reflects the __________ approach. (behavioral)
2. Charles Darwin was not a psychologist, but his work influenced the __________ approach to psychology. (evolutionary)
3. Assuming that people inherit mental disorders suggests a __________ approach. (biological)

Chapter 2 Research in Psychology

In Review: Methods of Psychology (p. 47)

1. The __________ method is most likely to use a double-blind design. (experimental)
2. Research on a new treatment method is most likely to begin with __________. (case studies)
3. Studying language by listening to people in public places is an example of __________ research. (naturalistic observation)

In Review: Descriptive and Inferential Statistics (p. 56)

1. The measure of central tendency that is most affected by extreme scores is the __________. (the mean)
2. A set of data with a high standard deviation will contain scores that are __________ variable than a set of data with a low standard deviation. (more)
3. Correlation coefficients of +.50 and −.50 indicate relationships that are of different strengths (True or False) __________. (false)

Chapter 3 Biological Aspects of Psychology

In Review: Neurons, Neurotransmitters, and Receptors (p. 71)

1. For one neuron to communicate with another, a __________ has to cross the __________ between them. (neurotransmitter; synapse)
2. The nervous system's main functions are to __________, __________, and __________ information. (receive; process; act on)
3. The two main types of cells in the nervous system are __________ and __________. (neurons; glial cells)

In Review: Organization of the Brain (p. 98)

1. The oldest part of the brain is the __________. (hindbrain)
2. Cells that operate as the body's twenty-four-hour "time clock" are found in the __________. (hypothalamus)
3. Memory problems seen in Alzheimer's disease are related to shrinkage of the __________ (hippocampus)

In Review: Classes of Neurotransmitters (p. 102)

1. The main neurotransmitter for slowing, or inhibiting, brain activity is __________. (GABA)
2. A group of neurons that use the same neurotransmitter is called a __________. (neurotransmitter system)
3. Which neurotransmitter's activity causes brain damage during a stroke? __________ (glutamate)

Chapter 4 Sensation

In Review: Hearing (p. 120)

1. Sound energy is converted to neural activity in an inner ear structure called the __________. (cochlea [or basilar membrane])
2. Hearing loss due to damage to hair cells or the auditory nerve is called __________. (nerve deafness)
3. How high or low a sound sounds is called __________ and is determined by the __________ of a sound wave. (pitch; frequency)

In Review: Seeing (p. 135)

1. The ability to see in very dim light depends on photoreceptors called __________. (rods)
2. Color afterimages are best explained by the __________ theory of color vision. (opponent-process)
3. Nearsightedness and farsightedness occur when images are not focused on the eye's __________. (retina)

In Review: Smell and Taste (p. 141)

1. The flavor of food arises from a combination of __________ and __________. (taste; smell)
2. Emotion and memory are linked especially closely to our sense of __________. (smell)
3. Perfume ads suggest that humans are affected by __________ that increase sexual attraction. (pheromones)

In Review: Body Senses (p. 151)

1. Gate control theory offers an explanation of why we sometimes do not feel __________. (pain)
2. Professional dancers look at the same spot as long as possible during repeated spins. They are trying to avoid the dizziness caused when the sense of __________ is overstimulated. (equilibrium)
3. Without your sense of __________, you would not be able to swallow food without choking. (touch)

Chapter 5 Perception

In Review: Principles of Perceptual Organization and Constancy (p. 176)

1. The movement we see in movies, videos, and DVDs is due to a perceptual illusion called ________. (the stroboscopic illusion)
2. People who have lost an eye also lose the depth cue called ________. (retinal disparity)
3. The grouping principle of ________ allows you to identify objects seen through a picket fence. (closure)

In Review: Mechanisms of Pattern Recognition (p. 182)

1. Your ability to read a battered old sign that has some letters missing is a result of ________ processing. (top-down)
2. When stimulus features match the stimuli we are looking for, ________ takes place. (recognition)
3. Schemas can create a ________ that makes us more likely to perceive stimuli in a particular way. (perceptual set)

Chapter 6 Learning

In Review: Basic Phenomena of Classical Conditioning (p. 207)

1. If a man's conditioned fear of spiders is triggered by the sight of other creatures that look like spiders, he is demonstrating stimulus ________. (generalization)
2. Because of ________, we are more likely to learn a fear of snakes than a fear of cars. (biopreparedness)
3. Feeling sad upon hearing a song associated with a long-lost relationship illustrates ________. (spontaneous recovery)

In Review: Reinforcement and Punishment (p. 221)

1. Taking an aspirin can relieve headache pain, so people learn to do so through the process of ________ reinforcement. (negative)
2. The "walk" sign that tells people it is safe to cross the street is an example of a ________ stimulus. (discriminative conditioned)
3. Response rates tend to be higher under ________ schedules of reinforcement than under ________ schedules. (ratio; interval)

Chapter 7 Memory

In Review: Models of Memory (p. 249)

1. The value of elaborative rehearsal over maintenance rehearsal has been cited as evidence for the ________ model of memory. (levels-of-processing)
2. Deliberately trying to remember something means using your ________ memory. (explicit)
3. Playing the piano uses ________ memory. (procedural)

In Review: Storing New Memories (p. 256)

1. If you looked up a phone number but forgot it before you could call it, the information was probably lost from ________ memory. (short-term)
2. The capacity of short-term memory is about ________ to ________ items. (five; nine)
3. Encoding is usually ________ in short-term memory and ________ in long-term memory. (acoustic; semantic)

In Review: Factors Affecting Retrieval from Long-Term Memory (p. 258)

1. Stimuli called ________ help you recall information stored in long-term memory. (retrieval cues)
2. If it is easier to remember something in the place where you learned it, you have ________ memory. (context-dependent)
3. The tendency to remember the last few items in a list is called the ________ effect. (recency)

In Review: Improving Your Memory (p. 279)

1. Using mnemonic strategies and the PQ4R system to better remember course material are examples of the value of ________ rehearsal. (elaborative)
2. "Cramming" illustrates ________ practice that usually leads to ________ long-term retention than ________ practice. (massed; poorer [or less]; distributed)
3. To minimize forgetting, you should review lecture notes ________ after a lecture ends. (immediately [or as soon as possible])

Chapter 8 Cognition and Language

In Review: Ingredients of Thought (p. 296)

1. Thinking is the manipulation of ________. (mental representations)
2. Arguments over what is "fair" occur because "fairness" is a ________ concept. (natural)
3. Your ________ of "hotel room" would lead you to expect yours to include a bathroom. (schema)

In Review: Solving Problems (p. 307)

1. People stranded without water could use their shoes to collect rain, but they may not do so because of an obstacle to problem solving called ________. (functional fixedness)
2. Because of the ________ heuristic, once sellers set a value on their house, they may refuse to take much less for it. (anchoring)
3. If you tackle a massive problem one small step at a time, you are using an approach called ________. (decomposition or means-end analysis)

Chapter 9 Consciousness

In Review: Sleep and Sleep Disorders (p. 350)

1. Jet lag occurs because of a disruption in a traveler's ________. (circadian rhythms [or sleep-wake cycle])
2. The importance of non-REM sleep is suggested by its appearance ________ in the night. (early)
3. The safest sleeping position for babies is ________. (face up)

In Review: Major Classes of Psychoactive Drugs (p. 365)

1. Physical dependence on a drug is a condition more commonly known as ________. (addiction)
2. Drugs that act as antagonists ________ the interaction of neurotransmitters and receptors. (block)
3. Drug effects are determined partly by what we learn to ________ the effects to be. (expect)

Chapter 10 Cognitive Abilities

In Review: Influences on IQ (p. 391)

1. Intelligence is influenced by both ________ and ________. (heredity; environment)
2. Children living in poverty tend to have ________ IQs than those in middle-class families. (lower)
3. IQs of children whose parents encourage learning tend to be ________ than those of children whose parents do not. (higher)

In Review: Analyzing Cognitive Abilities (p. 399)

1. The concepts of fluid and crystallized intelligence developed from research on the ____________ approach to intelligence. (psychometric)
2. Using fMRI scanning to relate memory skills to intelligence reflects which approach to intelligence? (information processing)
3. Which theory of intelligence highlights the fact that some people with low IQs can still succeed at complex tasks of daily living? (triarchic)

Chapter 11 Motivation and Emotion

In Review: Theories of Motivation (p. 420)

1. The fact that some people like roller coasters and other scary amusement park rides has been cited as evidence for the ____________ theory of motivation. (optimal arousal)
2. Evolutionary theories of motivation are modern outgrowths of theories based on ____________. (the instinct doctrine)
3. The value of incentives can be affected by ____________, ____________, and ____________ factors. (physiological [or biological]; cognitive; social)

In Review: Major Factors Controlling Hunger and Eating (p. 428)

1. People may eat when they are "full," suggesting that eating is not controlled by ____________ alone. (hunger)
2. People with ____________ know that they have a problem; those with ____________ nervosa tend not to. (bulimia; anorexia)
3. The best strategy for lasting weight loss includes regular ____________, as well as improved eating habits. (exercise)

In Review: Theories of Emotion (p. 456)

1. Research showing that there are pleasure centers in the brain has been cited in support of the ____________ theory of emotions. (Cannon-Bard)
2. The use of polygraphs in lie detection is based on the ____________ theory of emotions. (James-Lange)
3. The process of attribution is most important to ____________ theories of emotions. (cognitive)

Chapter 12 Human Development

In Review: Milestones of Cognitive Development in Infancy and Childhood (p. 479)

1. Research in cognitive development suggests that children form mental representations ____________ than Piaget thought they did. (earlier)
2. Recognizing that changing the shape of clay doesn't change the amount of clay is evidence of a cognitive ability called ____________. (conservation)
3. The appearance of object permanence signals the end of the ____________ period. (sensorimotor)

In Review: Social and Emotional Development During Infancy and Childhood (p. 499)

1. As part of their social development, children learn ____________, which tell them what patterns of appearance and behavior are associated with being male or female. (gender roles)
2. Teaching children to talk quietly in a restaurant is part of the process called ____________. (socialization)
3. Strict rules and the threat of punishment are typical of ____________ parenting. (authoritarian)

In Review: Milestones of Adolescence and Adulthood (p. 516)

1. The greatest threat to cognitive abilities in late adulthood is ____________ disease. (Alzheimer's)
2. Adolescents' ____________ identity may be more defining than their national citizenship. (ethnic)
3. Not stealing because "I might get caught" reflects the ____________ stage of moral reasoning. (preconventional)

Chapter 13 Health, Stress, and Coping

In Review: Stress Responses and Stress Mediators (p. 543)

1. The friends and family we can depend on to help us deal with stressors are called our ____________ network. (social support)
2. Fantasizing about winning money is a(n) ____________ focused way of coping with financial stress. (emotion)
3. Sudden, extreme stressors may cause psychological and behavioral problems known as ____________. (posttraumatic stress disorder)

In Review: Methods for Coping with Stress (p. 552)

1. Catastrophizing thoughts are best overcome through ____________ coping strategies. (cognitive)
2. The first step in coping with stress is to ____________ the sources and effects of your stressors. (identify)
3. True or false: It is best to rely on only one good coping strategy. ____________ (False)

Chapter 14 Personality

In Review: Major Approaches to Personality (p. 581)

1. Tests that measure the Five Factor Model's dimensions of personality are based on the ____________ approach to personality. (trait)
2. The role of learning is most prominent in the ____________ approach to personality. (social-cognitive)
3. Object relations and attachment theories are modern variants on ____________ personality theories. (psychodynamic)

In Review: Personality Tests (p. 590)

1. Projective personality measures are based on the ____________ approach to personality. (psychodynamic)
2. The NEO-PI-R and the MMPI-2 are examples of ____________ tests. (nonprojective)
3. Most personality researchers use ____________ tests in their work. (nonprojective)

Chapter 15 Psychological Disorders

In Review: Anxiety, Somatoform, and Dissociative Disorders (p. 620)

1. Concern that it may be triggered by media stories or therapists' suggestions has made ____________ the most controversial of the dissociative disorders. (dissociative identity disorder)
2. A person who sleepwalks but is not able to walk when awake is showing signs of ____________. (conversion disorder)
3. Panic disorder sometimes leads to another anxiety disorder called ____________. (agoraphobia)

In Review: Affective Disorders (p. 623)

1. The risk of suicide is associated with ____________ more than with any other symptom of disorder. (depression)
2. Cyclothymic personality is the bipolar version of ____________. (dysthymic disorder)
3. Women are ____________ likely than men to try suicide, but men are ____________ likely to succeed. (more; more)

In Review: Schizophrenia (p. 633)

1. The ____________ approach forms the basis of the vulnerability theory of schizophrenia. (diathesis-stress)

2. Hallucinations are ____________ symptoms of schizophrenia; lack of emotion is a ____________ symptom. (positive; negative)
3. Patients with schizophrenia who were able to finish school are ____________ likely to show improvement. (more)

Chapter 16 Treatment of Psychological Disorders

In Review: Approaches to Psychological Treatment (p. 671)

1. Object relations therapy and interpersonal therapy are both contemporary examples of the ____________ approach to psychological treatment. (psychodynamic)
2. Imagining increasingly fear-provoking stimuli is a ____________ treatment method called ____________. (behavioral; systematic desensitization)
3. Reflection is an interviewing technique associated mainly with the ____________ approach to treatment. (humanistic [or nondirective])

In Review: Biological Treatments for Psychological Disorders (p. 687)

1. Electroconvulsive shock therapy is used ____________ often now than it was in the 1950s. (less)
2. Anxiolytics are used mainly in the treatment of ____________. (anxiety)
3. Tardive dyskinesia is a movement disorder sometimes caused by ____________ drugs. (neuroleptic)

Chapter 17 Social Cognition

In Review: Some Biases in Social Perception (p. 708)

1. The fundamental attribution error appears to be somewhat less likely to occur among people in ____________ cultures. (collectivist)
2. First impressions form ____________, but change ____________. (quickly; slowly)
3. If you believed that immigrants' successes are due to government help but that their failures are due to laziness, you would be committing the ____________ error. (ultimate attribution error)

In Review: Forming and Changing Attitudes (p. 713)

1. According to the elaboration likelihood model, people are more likely to pay close attention to the content and logic of a persuasive message if the ____________ route to attitude change has been activated. (central)
2. Holding attitudes that are similar to those of your friends illustrates the importance of ____________ in attitude formation (learning)
3. According to cognitive dissonance theory, we tend to reduce conflict between attitudes and behaviors by changing our ____________. (attitudes)

Chapter 18 Social Influence

In Review: Types of Social Influence (p. 742)

1. Joining the end of a ticket line is an example of ____________, whereas forming two lines when a theater employee requests it is an example of ____________. (conformity; compliance)
2. Seeing someone disobey a questionable order makes people ____________ likely to obey the order themselves. (less)
3. Pricing your used car for more than you expect to get, then agreeing to reduce it to make a sale, is an example of the ____________ approach to gaining compliance. (door-in-the-face)

In Review: Assistance (p. 758)

1. If you could save only one person from a burning house, the ____________ theory of assistance would predict that it would be your own child rather than, say, a grandparent. (evolutionary)
2. Are you more likely to receive assistance in a nearly empty bus or a crowded bus terminal? ____________. (A nearly empty bus)
3. People who have empathy for others are ____________ likely to be helpful. (more)

Chapter 19 Industrial/Organizational Psychology

In Review: Assessing People, Jobs, and Job Performance (p. 777)

1. Lists of critical incidents are contained in ____________-focused employee rating forms. (behavior)
2. A potential employer might use a two-day ____________ to measure your skill at the job you want. (assessment center)
3. In general, ____________ interviews are more useful in employee selection than ____________ interviews. (structured; unstructured)

In Review: Recruiting, Selecting, and Training Employees (p. 783)

1. Employees tend to remember more from a training program when it is set up on a ____________ rather than a ____________ schedule. (distributed; massed)
2. Depending on "walk-in" applications is usually acceptable when hiring ____________-level employees. (low)
3. Assuring that your hiring criteria actually predict employees' job performance requires a ____________. (validation study)

Chapter 20 Neuropsychology

In Review: Foundations of Neuropsychology (p. 810)

1. A person who studies individual patients to determine what kind of brain damage each one happens to have is called a ____________. (clinical neuropsychologist)
2. The case of "Tan" helped to establish the principle of ____________. (localization of function)
3. In alexia without agraphia, the brain areas that control reading and writing are intact but cannot interact. This condition is called a ____________. (disconnection syndrome)

In Review: Mechanisms of Brain Dysfunction (p. 813)

1. The brain floats in a bath of ____________ inside the skull. (cerebrospinal fluid)
2. The brain needs a constant flow of fresh ____________ all the time. (blood)
3. Cerebrovascular accidents rank as the number ____________ cause of death in the United States. (three)

In Review: Major Neuropsychological Problems (p. 829)

1. A patient who has become forgetful but has no problems in other areas of cognitive function may be said to have ____________. (mild cognitive impairment)
2. A dementia patient whose hippocampus is relatively intact and can still form new memories probably has ____________ dementia. (vascular)
3. A patient with thiamine deficiency who is forgetful but makes up memories and believes they are real probably has ____________. (Korsakoff's syndrome)

APPENDIX B

Behavioral Genetics

Think about some trait that distinguishes you from other people, a trait on which you feel you are well above or well below average. Perhaps it relates to your skill at sports, languages, or music, or maybe to your fearfulness, sociability, or other aspects of your personality. Have you ever wondered what made you the way you are? If you are shy, for example, it is easy to think of possible environmental explanations. Perhaps you are shy because as a child you had few opportunities to meet new children or because you had embarrassing or unpleasant experiences when you did meet them. Maybe you have shy parents who served as the role models you imitated. Such environmental explanations are certainly reasonable, but it is also possible that you inherited a disposition toward shyness from your parents. It is even more likely that both inheritance and environment contributed to your shyness.

Topics such as these are addressed by researchers in the field of *behavioral genetics*, the study of how genes affect behavior (see the chapter on research in psychology). These researchers have developed methods to explore genetic, as well as environmental, origins of behavioral differences among people. The results of behavioral genetics research make it clear that heredity has a significant influence, not just on shyness but on personality more generally, on cognitive abilities, on psychological disorders, and on many other aspects of human behavior and mental processes. However, behavioral genetics is just as much the study of environment as of genetics. In the process of trying to disentangle genetic from environmental factors, researchers have made several important discoveries about the impact of the environment.

In this appendix, we discuss behavioral genetics in more detail than we did in the chapter on research in psychology. We begin with a review of the biochemical mechanisms underlying genetics and heredity. We then offer a brief history of genetic research in psychology, followed by a discussion of what research on genetic influences can and cannot tell us about the origins of human differences. Finally, we describe some findings from behavioral genetics research that illuminate several important aspects of human behavior and mental processes.

The Biology of Genetics and Heredity

What does it mean to say that someone has inherited some physical feature or behavioral trait? The answer lies in **genetics**, the biology of inheritance. The story begins with the biochemistry of the human body and with the chromosomes contained within each of the body's cells. Most human cells contain forty-six chromosomes, arranged in twenty-three matching pairs. These **chromosomes** are long, thin structures that are made up of thousands of genes. **Genes** are the biochemical units of heredity that govern the development of an individual by controlling the synthesis of protein. They are composed of **DNA (deoxyribonucleic acid)**—strands of sugar, phosphate, and four kinds of nitrogen-containing molecules twisted around each other in a double spiral (see Figure 1).

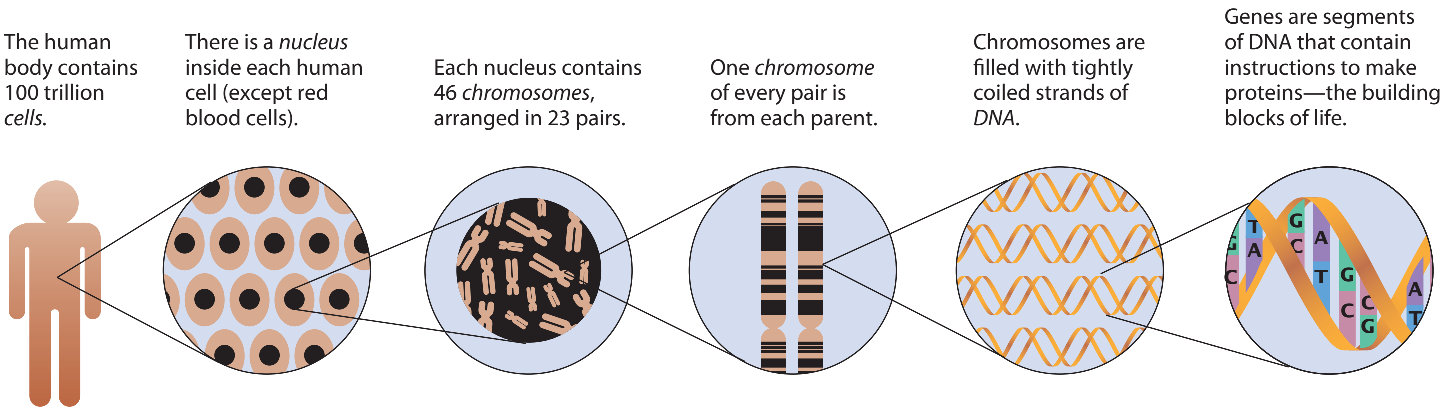
The exact mechanism by which genes work is still the subject of intensive research. So far, we know that the structure of a gene—as seen in the particular order in which the four nitrogen-containing molecules are arranged in that segment of DNA—determines, through the production of *RNA(ribonucleic acid)*, which protein the gene will produce. (In fact, a typical gene may produce any one of several proteins, depending on other factors.) Protein molecules, in turn, form the physical structure of each cell and also direct the activity of the cell. So DNA essentially provides a coded message that provides a blueprint for constructing every aspect of a physical human being, including eye color, height, blood type, inherited disorders, and the like—and all in less space than the period that ends this sentence.

genetics The biology of inheritance.

chromosomes Long, thin structures in every biological cell that contain genetic information.

genes The biological instructions, inherited from both parents and located on the chromosomes, that provide the blueprint for physical development.

DNA (deoxyribonucleic acid) The material that makes up chromosomes and provides the genetic code.



The human body contains 100 trillion *cells.*
There is a *nucleus* inside each human cell (except red blood cells).
Each nucleus contains 46 *chromosomes*, arranged in 23 pairs.
One *chromosome* of every pair is from each parent.
Chromosomes are filled with tightly coiled strands of *DNA*.
Genes are segments of DNA that contain instructions to make proteins—the building blocks of life.

FIGURE 1

Genetic Building Blocks

Only about 3 percent of DNA contains genes, though some of the rest of it affects how and when each gene actually works to guide the production of proteins. Together, genes and non-gene material in DNA essentially determine all the inherited aspects of our physical bodies, and influence many of our behavioral characteristics, too.

New cells are constantly being produced by the division of existing cells. Most of the body's cells divide through a process called *mitosis*, in which the cell's chromosomes duplicate themselves so that each new cell contains copies of the twenty-three pairs of chromosomes in the original.

A different kind of cell division occurs when a male's sperm cells and a female's egg cells (called *ova*) are formed. This process is called *meiosis*. In meiosis, the chromosome pairs are not copied. Instead, they are randomly split and rearranged, leaving each new sperm and egg cell with just one member of each chromosome pair, or twenty-three single chromosomes. No two of these special new cells are quite the same, and none contains an exact copy of the person who produced it. So at conception, when a male's sperm cell fertilizes the female's ovum, a truly new cell is formed. This fertilized cell, called a *zygote*, carries twenty-three pairs of chromosomes—half of each pair from the mother and half from the father. The zygote represents a unique heritage, a complete genetic code for a new person that combines genes from both parents. As described in the chapter on human development, the zygote divides first into copies of itself and then into the billions of specialized cells that form a new human being.

Whether or not genes express themselves in the individual who carries them depends partly on whether they are dominant or recessive. *Dominant* genes are outwardly expressed whenever they are present. *Recessive* genes are expressed only when they are paired with a similar gene from the other parent. For example, phenylketonuria (PKU)—a disorder seen in about 1 in 10,000 newborns—is caused by a recessive gene. When inherited from both parents, this gene disrupts the body's ability to control phenylalanine, an amino acid found in milk and other foods. As a result, this acid is converted into a toxic substance that can cause severe intellectual disability. (Discovery of this genetic defect made it possible to prevent such disability in children with PKU simply by making sure they did not consume foods high in phenylalanine.) PKU is one of more than 4,000 single-gene disorders, but in fact, relatively few human characteristics are controlled by just one gene. Most characteristics are **polygenic traits**, meaning that they are controlled by many genes. Even a person's eye color and height are affected by more than one gene.

The genes contained in the forty-six chromosomes inherited from parents make up an individual's **genotype**. Because identical twins develop from one fertilized egg cell, they are described as *monozygotic*; they have exactly the same genotype. So why don't all identical twins look exactly alike? Because they do not have exactly the same environment. An individual's **phenotype** is the set of observable characteristics that result from the combination of heredity and environment. In twins and nontwins alike, the way people actually look and act is influenced by the combination of genes they carry, as well as by environmental factors—in other words, by both nature and nurture.

polygenic traits Characteristics that are determined by more than one gene.

genotype The full set of genes, inherited from both parents, contained in twenty-three pairs of chromosomes.

phenotype How an individual looks and acts, which depends on how inherited characteristics interact with the environment.

A Brief History of Genetic Research in Psychology

The field now known as behavioral genetics began in the late 1800s with the work of Sir Francis Galton. A cousin of Charles Darwin, Galton was so impressed with Darwin's book on evolution that he decided to study heredity in the human species, especially as it relates to human behavior. Galton suggested the family, twin, and adoption study designs that are the mainstays of human behavioral genetics research today (see the chapter on research in psychology). He even coined the phrase *nature-nurture* to refer to genetic and environmental influences. Galton's most famous behavioral genetics study was one in which he showed that genius runs in families. Unfortunately, Galton went too far in interpreting the evidence from this family study when he concluded that "nature prevails enormously over nurture" (Galton, 1883, p. 241). As noted in the chapter on research in psychology, family members can be similar to each other because of environmental, as well as hereditary, factors. So similarity seen among family members with regard to characteristics such as genius could be traced to the environments family members share, to their shared genes, or both. Still, Galton's work helped to focus psychologists' interest on the influence of genetics and on the need to separate nature from nurture in drawing conclusions about why people resemble or differ from each other.

The first two studies aimed at separating nature and nurture by studying twins and adoptees were conducted in 1924. Both focused on IQ, and both suggested the existence of an important genetic contribution to intelligence. However, research on the influence of genetics on behavior and mental processes was inhibited for a while because of two factors. The first was the impact of John B. Watson's behaviorism, which, as mentioned in the introductory chapter, suggested that we are only what we learn. In 1925, Watson insisted "that there is no such thing as an inheritance of capacity, talent, temperament, mental constitution and characteristics. These things again depend on training that goes on mainly in the cradle" (Watson, 1925, pp. 74–75). The second factor that discouraged attention to human genetics was eugenics, which had become mainstream thinking in the United States as well as Great Britain and elsewhere. This view led to compulsory sterilization of those considered "unfit" and reached its extreme in Germany under the Nazi regime of Adolf Hitler. The idea that certain groups of people were "genetically inferior" led to the Holocaust during World War II, a campaign of genocide during which millions of Jews and other allegedly "inferior" people were killed.

Genetic research on human behavior was reduced to a trickle during the 1930s and 1940s, but research with animals led, in 1960, to publication of the first behavioral genetics textbook (Fuller & Thompson, 1960) and to signs of increased interest in human genetics. In 1963 an influential article reviewed family, twin, and adoption findings and concluded that genetic factors are an important influence on IQ (Erlenmeyer-Kimling & Jarvik, 1963). Around the same time, the first adoption study of schizophrenia pointed to a strong genetic contribution to that disorder (Heston, 1966).

In the early 1970s, however, interest in human behavioral genetics among psychologists faded again, this time because of reactions to two publications. The first was a paper by Arthur Jensen in which he suggested that differences in average IQ between blacks and whites might be partly due to genetic factors (Jensen, 1969). The second was a book by Richard Herrnstein in which he argued that genetics might contribute to social class differences (Herrnstein, 1973). The furious public and scientific response to these publications—which included branding the authors as racists—inhibited genetic research in psychology, even though very few behavioral geneticists were studying ethnic or class differences. It was not until later in the 1970s and into the 1980s that major genetic studies were again conducted in psychology.

Today most psychologists recognize the role of both genetics and environment in behavior and mental processes, including the controversial area of cognitive abilities. In fact, in 1992 the American Psychological Association selected behavioral genetics as one of two themes best representing the past, present, and especially the future of psychological research (Plomin & McClearn, 1993). To some, though, the study of human behavioral genetics still carries a hint of racism and class elitism. These concerns were resurrected by a book titled *The Bell Curve,* which considers the role of genetics in ethnic differences in intelligence and the implications of intelligence for social class structure (Herrnstein & Murray, 1994). Fortunately, reaction to that book has not altered the balanced perspective that recognizes the importance of nature as well as nurture in psychology.

The Focus of Research in Behavioral Genetics

Much of the controversy about behavioral genetics and about nature and nurture in general comes from misunderstandings about what behavioral genetics researchers study and, more specifically, what it means to say that genes influence behavior.

For one thing, behavioral genetics is the study of genetic and environmental factors that are responsible for *differences* among individuals or groups of individuals, not for the characteristics of any single individual. Consider height, for example. Identical twins are much more similar in height than are fraternal twins (who share no more genes than other siblings), and individuals who are genetically related but raised separately are just as similar in height as are relatives who are raised together. Further, genetically unrelated individuals who are raised together are no more similar in height than random pairs of individuals. These data suggest, not surprisingly, that height is highly *heritable*. This means that much of the *variability* in height that we see among people—actually about 80 percent of it—can be explained by genetic differences among them rather than by environmental differences. (It does not mean that a person who is six feet tall grew 80 percent of that height because of genes and the other 20 percent because of environment!) It also follows that if a person is, say, shorter than average, genetic reasons are probably the primary cause. We say "probably" because finding a genetic influence on height involves referring only to the origins of average individual differences in the population. So although the difference in people's heights is attributable mainly to genetic factors, a particular person's height could be due mainly to an early illness or other growth-stunting environmental factors. For example, Hattie and Samantha Peters, a pair of identical twins, were exposed to a rare condition in their mother's womb that deprived Samantha of vital nutrients. As a result, Hattie is 5 feet 4 inches tall, but Samantha is only 4 feet 8 inches (Taggart, 2004).

To see how the logic of behavioral genetics applies to conclusions about psychological characteristics, suppose a researcher found that the heritability of a certain personality trait is 50 percent. This result would mean that approximately half of the differences among people on that trait are attributable to genetic factors. It would not mean that each person inherits half of the trait and gets the other half from environmental influences. As in our height example, behavioral geneticists want to know how much variability among people can be accounted for by genetic and environmental factors. The results of their research allow generalizations about the influence of nature and nurture on certain characteristics, but those generalizations do not necessarily apply to the origin of a particular person's characteristics.

Another misconception about genetic influences is that they are "hard-wired" and thus have inevitable effects. So in most cases, having a particular genetic makeup does not guarantee that a person will develop a particular condition, but only that the person's *chance* of developing that condition is higher or lower. Further, complex traits—intelligence, for example—are influenced by many genes, as well as by many environmental factors. So genetic influence means just that—influence. Genes can affect a trait without completely determining whether or not it will appear.

The Role of Genetic Factors in Psychology

In the following sections, we consider behavioral genetics research results that tell a little more of the story about how genes can have an impact on behavior and mental processes.

Genetic Influences over the Life Span

One particularly interesting finding about genetic influences on general cognitive ability is that these influences continue to increase throughout the life span (McGue et al., 1993; Plomin, 1986). That is, the proportion of individual differences (variance) in IQ scores that can be explained by genetic factors increases from 40 percent in childhood to 60 percent in adolescence and young adulthood and then to 80 percent later in life. This increase in the magnitude of genetic influence can be seen, for example, in the expanding difference between IQ correlations for identical twins and those for fraternal twins: Identical twins become more similar in IQ over the life span, whereas fraternal twins become less similar as the years go by. This finding is all the more interesting for overturning the common assumption that environmental influences become increasingly important as accidents, illnesses, and other experiences accumulate throughout life.

How can it be that genetic influences become more important over time? One possible explanation is that, as discussed later, genetic predispositions lead people to select, and even create, environments that foster the continued development of their genetically influenced abilities.

Genes Affecting Multiple Traits

Behavioral genetics research has also revealed that genes affecting one trait can sometimes affect others as well. For example, it appears that the same genetic factors that affect anxiety also affect depression (Kendler, Neale, et al., 1992; Kendler et al., 2003). So if we could identify specific genes responsible for genetic influences on anxiety, we would expect to find that the same genes were associated with the appearance of depression. Similarly, genetic factors affecting substance dependence are highly correlated with genetic factors affecting antisocial behavior and impulsive style (Kendler et al., 2003; Krueger et al., 2002).

A similar finding has emerged for cognitive ability and scholastic achievement. Tests of scholastic achievement show almost as much genetic influence as do tests of cognitive ability. Moreover, tests of scholastic achievement correlate substantially with tests of cognitive ability. To what extent is a common set of genes responsible for this overlap? Research suggests that the answer is “almost entirely.” It appears that the genes that influence performance on mental ability tests are the same ones that influence students’ performance at school (Wadsworth, 1994).

Identifying Genes Related to Behavior

One of the most exciting new developments in behavioral genetics involves identifying the specific genes responsible for genetic influences in psychology. For example, there are hundreds of rare, single-gene disorders that affect behavior. One of these is *Huntington’s disease*, an ultimately fatal disorder that involves loss of motor control and progressive deterioration of the central nervous system. Huntington’s disease emerges only in adulthood, beginning with personality changes, forgetfulness, and other behavioral problems. It is caused by a single dominant gene whose identification in 1983 made it possible to determine who will get this disease—even though the biochemical mechanisms underlying the disorder are still not fully understood and prevention is not yet possible.

Researchers are also tracking down the several genes involved in the appearance of Alzheimer’s disease. (As described in the chapter on biological aspects of psychology, this disease causes memory loss and increasing confusion in many older people.) One of these, a gene that contributes to the risk for late-onset Alzheimer’s disease, was identified in 1993. This gene increases the risk for Alzheimer’s disease about fivefold, but its presence is neither necessary nor sufficient for the disease to appear. That is, many people with Alzheimer’s disease do not have the gene, and many people with the gene do not have the disease. Nonetheless, this gene is by far the strongest risk factor known for Alzheimer’s disease, and its discovery marks the beginning of a new era in which specific genes—or regions of DNA near specific genes—will be identified as influencing disorders and psychological traits.

Progress in identifying specific genes in humans has been slower than expected, in part because research ethics and common sense prevent the use of selective breeding. Accordingly, human studies have lacked the statistical power needed to detect relatively weak but still potentially important genetic influences on behavior. However, the more powerful genetic research techniques available in studies of animals have identified several genes associated, for example, with fearfulness (Saiz et al., 2008), with sensitivity to drugs such as alcohol (Wall et al., 2005), and with various aspects of learning and memory (Wahlsten, 1999). In most cases, however, these associations are tendencies rather than certainties—they are indicators that are not necessarily definitive.

Today’s efforts to identify genes related to human behavior are being aided by advances flowing from the Human Genome Project, which in early 2001 succeeded in identifying the sequence of most of the 3 billion "letters" of DNA in the human genome. One of the most surprising findings of that project so far is that the human genome appears to contain only about 20,000 to 25,000 genes—less than half the number expected, and a number that is similar to the estimates for animals such as mice and worms (International Human Genome Sequencing Consortium, 2004). Does this smaller-than-expected number of human genes mean that there are too few to influence all aspects of human behavior, and that the environment (nurture) must be even more important than we thought in this regard? Not necessarily. It may be that the greater complexity seen in human behavior versus, say, mouse behavior stems not from the number of genes we have but from the greater complexities involved in decoding our genes into proteins. Human genes, more than the genes of other species, are spliced in alternative ways to create a greater variety of proteins. It may be this more subtle variation in genes—not the number of genes—that is responsible for differences between mice and people. This possibility has important implications for behavioral genetics because if the obvious differences between humans and other species are due to subtle DNA differences, then individual differences *within* our species—in other words, among people—are likely to involve genetic factors that are even more subtle and hard to find.

Fortunately, new techniques are available that make it possible to detect DNA differences for many thousands of genes simultaneously. These techniques will help in identifying genes related to behavior, a process which will fill in the causal picture about a variety of characteristics and disorders that are influenced by many genes and many environmental factors. But it might not just be the actions of multiple genes that have a major impact on behavior. It might also be a gene-environment interaction—the combination of a specific gene in a specific environment—that has the greatest influence on behavior. Examples of such interactions appear in research by Avshalom Caspi and his colleagues (Caspi et al., 2002; Caspi et al., 2003; Jaffee et al., 2007). In one study, they found that children living in an environment in which there is abuse or other maltreatment were at increased risk for displaying antisocial behavior in later life. But the at-risk children who also had a particular gene did not become antisocial. It was as if the gene protected them against this common consequence of childhood maltreatment. A second study showed that, although depression and suicide are often associated with stressful life events, variation in a particular gene could predict whether people became depressed and suicidal in response to such events (Caspi et al., 2003). Understanding how multiple genes combine to influence behavior and analyzing gene-environment interactions will continue to be active and exciting areas of research in behavioral genetics.

Behavioral Genetics and Environmental Influences

As suggested earlier, research on genetic influences in psychology has also provided some of the best evidence for the importance of environmental influences. It has shown that even though genetic influences are important, they cannot explain everything about human behavior.

For example, twin and adoption studies have provided evidence of the importance of genetic factors in schizophrenia, and as a result, many researchers are now trying to identify the specific genes responsible. Enthusiasm for genetic explanations of schizophrenia makes it easy to forget, however, that environmental factors can be at least as important as genes. As described in the chapter on psychological disorders, when one member of an identical-twin pair is schizophrenic, the chances are about 40 percent that the other member of the pair is also schizophrenic, a rate that is much higher than the 1 percent rate of schizophrenia in the general population. This result surely provides evidence of a strong genetic contribution to schizophrenia, but it also suggests that schizophrenia is strongly influenced by the environment. After all, most of the time, the identical twin of a person with schizophrenia will not display the disorder. Such differences within pairs of identical twins can be due only to the operation of environmental factors.

In fact, research generally suggests that genetic factors account for only about half of the variance among individuals for psychological characteristics such as personality and psychopathology. This means that at least half of the variance among individuals on these characteristics is due to environmental factors. These environmental—or more properly, *nongenetic*—factors encompass everything other than genetic inheritance. They include such biological factors as prenatal events, nutrition, and illnesses, as well as more traditional environmental factors such as parenting, schooling, and peer influences.

In short, one of the most important findings to emerge from behavioral genetics research has concerned the environment, not genetics. That research suggests that the most important environmental influences are likely to be those that different family members do not share (Plomin, Asbury, & Dunn, 2001). Psychologists want to find out more about these *nonshared factors* and how they act to create differences in children—twins or not—who grow up in the same family.

So far, research on this topic has shown that children may grow up in the same family but that they experience quite different environments, especially in relation to their parents (Brody, 2004). Siblings perceive that their parents treat them very differently—and observational studies back up these perceptions of differential treatment (Plomin, Asbury, & Dunn, 2001). Even events such as parental divorce, which would seem to be shared by all children in the family, appear to be experienced differently by each child, depending especially on age, personality, and the nature of the relationship with each parent.

TRY THIS

Research is also beginning to focus on environmental influences beyond the family—such as relationships with teachers or friends—which are even more likely than home-related factors to vary among siblings. If you have a brother or sister, think about a psychological trait on which you and your sibling differ—confidence, for example. Why do you think you two are different on that trait? Perhaps one of you experienced a loss of self-confidence when faced with the demands of an impatient grade-school teacher or after being betrayed by a childhood friend. Did these differing experiences occur randomly and thus make you considerably more confident or less confident than your sibling? Or is it possible that differences in your genetic makeups helped bring about these different experiences? Unless you and your sibling are identical twins, you share only about 50 percent of your genes. Perhaps genetically influenced differences between the two of you—in emotionality or other aspects of temperament, for example—caused parents, peers, and others to respond to each of you differently. This brings us to the second major discovery about the environment to emerge from research on behavioral genetics: Environmental influences associated with differences between siblings might actually be the *result* of genetic differences between the siblings.

Most of the measures used by psychologists to assess what might be thought of as environmental factors have now been shown to be influenced by genetic factors (Plomin & Bergeman, 1991). These include measures such as adolescents' ratings of how their parents treated them, observations of parent-child interactions, and questionnaires about life events and social support. If scores on measures such as these reflected only environmental factors, then the scores of identical twins should be no more similar to each other than those of fraternal twins. By the same token, there should be little similarity in environmental-experience measures for genetically related individuals who grew up in different families.

The results reported by behavioral geneticists do not fit these expectations. For example, parents differ in terms of how responsive they are to their children, but these differences in responsiveness correlate with the children's cognitive ability—a trait that has a clear genetic component. So, as described in the chapters on cognitive abilities and human development, parental responsiveness can influence cognitive development, and—as behavioral genetics research suggests—children's inherited cognitive abilities can alter the responsiveness of their parents. That is, parents tend to be more responsive to bright children who ask lots of questions and are interested in the answers.

Outside the family, too, genetic factors appear to play a role in generating environmental experiences (Harris, 1998). For example, research on the characteristics of children's peer groups shows that children tend to choose their friends—and to be chosen as friends—partly on the basis of genetically influenced traits, such as mental ability and temperament (Manke et al., 1995). Several studies also suggest that genetic factors can increase or decrease the likelihood of family conflicts and other social stressors that threaten one's physical and psychological well-being (Reiss et al., 2000). In addition, genetic influences on personality can account for the genetic effects seen in adults' reports about their family environments when growing up (Krueger, Markon, & Bouchard, 2003).

An important implication of genetic influences on environmental events is that measuring the impact of family relationships, peer influences, and other environmental factors on behavior and mental processes may be less straightforward than psychologists thought. A measure that is aimed at assessing an "environmental" factor may nonetheless be affected by the genetic characteristics of the people being studied.

In human development, nature and nurture work together. Children select, modify, and create environments that are correlated with their genetic inclinations. As developmental psychologists have long argued, children are not formless blobs of clay passively molded by the environment. Rather, they are active participants in their experiences. The new findings we have described here suggest that genetics plays an important role in those experiences.

SUMMARY

Behavioral genetics is the study of how genes affect behavior.

The Biology of Genetics and Heredity

Research on the ways in which nature and nurture interact to shape behavior and mental processes requires a knowledge of *genetics,* the biology of inheritance. The genetic code that transmits characteristics from one generation to the next is contained in the *DNA (deoxyribonucleic acid)* that makes up the *genes* that in turn make up *chromosomes.* Dominant genes are expressed whenever they are present; recessive genes are expressed only when inherited from both parents. Most human characteristics are controlled by more than one gene; they are *polygenic traits*. The genes in a person's forty-six chromosomes make up the *genotype*. The *phenotype*—how people actually look and act—is influenced by genes and the environment.

A Brief History of Genetic Research in Psychology

Sir Francis Galton's work in the nineteenth century helped to stimulate psychologists' interest in the influence of genetics on behavior. The popularity of research in this area has waxed and waned over the years, but today most psychologists recognize the role of genetic, as well as environmental, influences on many aspects of behavior and mental processes.

The Focus of Research in Behavioral Genetics

Behavioral genetics research identifies the genetic and environmental factors responsible for differences among individuals, not for the characteristics of a particular person. Although genes can influence a trait, they may not completely determine whether that trait appears.

The Role of Genetic Factors in Psychology

Genetic factors probably influence, to some extent, every aspect of behavior and mental processes.

Genetic Influences over the Life Span

Genetic influences on general cognitive ability appear to increase over time, possibly because genetic predispositions lead people to select and even create environments that foster the continued development of abilities that are in line with those predispositions.

Genes Affecting Multiple Traits

Genes that affect one trait, such as anxiety, can sometimes also affect other traits, such as depression.

Identifying Genes Related to Behavior

Current research in behavioral genetics, aided by findings from the Human Genome Project, is identifying specific genes responsible for specific characteristics—especially rare, single-gene disorders such as Huntington's disease. It is also illuminating gene-environment interactions.

Behavioral Genetics and Environmental Influences

Research in behavioral genetics has actually provided evidence for the importance of environmental influences, too, because the research shows that genetics alone cannot account for such characteristics as intelligence, personality, and psychological disorders. Some of the most important environmental influences are likely to be those that members of the same family do not share. In short, neither nature nor nurture is conducting the performance of the other: They are playing a duet.

APPENDIX C

Statistics in Psychological Research

Understanding and interpreting the results of psychological research depends on *statistical analyses,* which are methods for describing and drawing conclusions from data. The chapter on research in psychology introduced some terms and concepts associated with *descriptive statistics*—the numbers that psychologists use to describe and present their data—and with *inferential statistics*—the mathematical procedures used to draw conclusions from data and to make inferences about what they mean. Here, we present more details about these statistical analyses that will help you to evaluate research results.

Describing Data

To illustrate our discussion, consider a hypothetical experiment on the effects of incentives on performance. The experimenter presents a list of mathematics problems to two groups of participants. Each group must solve the problems within a fixed time, but for each correct answer, the low-incentive group is paid ten cents, whereas the high-incentive group gets one dollar. In **null hypothesis testing**, the hypothesis to be tested is the assertion that the independent variable manipulated by the experimenter will have no effect on the dependent variable measured by the experimenter. In this case, the null hypothesis is that the size of the incentive (the independent variable) will not affect performance on the mathematics task (the dependent variable).

Assume that the experimenter has gathered a representative sample of participants, assigned them randomly to the two groups, and done everything possible to avoid the confounds and other research problems discussed in the chapter on research in psychology. The experiment has been run, and the psychologist now has the data: a list of the number of correct answers given by each participant in each group. Now comes the first task of statistical analysis: describing the data in a way that makes them easy to understand.

TABLE 1 A Simple Data Set

Here are the test scores obtained by thirteen participants performing under low-incentive conditions and thirteen participants performing under high-incentive conditions.

Low Incentive	High Incentive
4	6
6	4
2	10
7	10
6	7
8	10
3	6
5	7
2	5
3	9
5	9
9	3
5	8

The Histogram

The simplest way to describe the data is to draw up something like Table 1, in which all the numbers are simply listed. After examining the table, you might notice that the high-incentive group seems to have done better than the low-incentive group, but this is not immediately obvious. The difference might be even harder to see if more participants had been involved and if the scores included three-digit numbers. A picture is worth a thousand words, so a better way of presenting the same data is in a picture-like graphic known as a **histogram** (see Figure 1).

Construction of a histogram is simple. First, divide the scale for measuring the dependent variable (in this case, the number of correct answers) into a number of categories, or "bins." The bins in our example are 1–2, 3–4, 5–6, 7–8, and 9–10. Next, sort the raw data into the appropriate bin. (For example, the score of a participant who had 5 correct answers would go into the 5–6 bin, a score of 8 would go into the 7–8 bin, and so on.) Finally, for each bin, count the number of scores in that bin and draw a bar up to the height of that number on the vertical axis of a graph. The resulting set of bars makes up the frequency histogram.

Because we are interested in comparing the scores of two groups, there are separate histograms in Figure 1: one for the high-incentive group and one for the low-incentive group. Now the difference between groups that was difficult to see in Table 1 becomes clearly visible: High scores were more common among people in the high-incentive group than among people in the low-incentive group.

Histograms and other pictures of data are useful for visualizing and better understanding the "shape" of research results, but in order to analyze those results statistically,

null hypothesis testing Evaluating whether the independent variable manipulated by the experimenter will have no effect on the dependent variable measured by the experimenter.

histogram A graphic presentation of data that consists of a set of bars, each of which represents how frequently different scores or values occur in a data set.

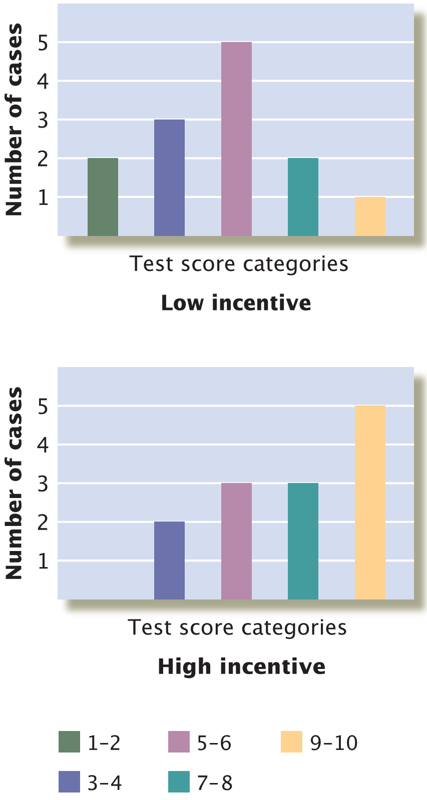

FIGURE 1
Histograms
The height of each bar of a histogram represents the number of scores falling within each range of score values. The pattern formed by these bars gives a visual image of how research results are distributed.

descriptive statistics Numbers that summarize a set of research data.

range A measure of variability that is the difference between the highest and the lowest values in a data set.

standard deviation (SD) A measure of variability that is the average difference between each score and the mean of the data set.

we need to use other ways of handling the data that make up these graphic presentations. For example, before we can tell whether two histograms are different statistically or just visually, the data they represent must be summarized using **descriptive statistics**.

Descriptive Statistics The four basic categories of descriptive statistics (1) measure the number of observations made; (2) summarize the typical value of a set of data; (3) summarize the spread, or variability, in a set of data; and (4) express the correlation between two sets of data.

N The easiest statistic to compute, abbreviated as N, simply describes the number of observations that make up the data set. In Table 1, for example, $N = 13$ for each group, or 26 for the entire data set. Simple as it is, N plays a very important role in more sophisticated statistical analyses.

Measures of Central Tendency It is apparent in the histograms in Figure 1 that there is a difference in the pattern of scores between the two groups. But how much of a difference? What is the typical value, the *central tendency*, that represents each group's performance? As described in the chapter on research in psychology, there are three measures that capture this typical value: the mode, the median, and the mean. Recall that the *mode* is the value or score that occurs most frequently in the data set. The *median* is the halfway point in a set of data: Half the scores fall above the median, half fall below it. The *mean* is the arithmetic average. To find the mean, add up the values of all the scores and divide that total by the number of scores.

Measures of Variability The variability, or spread, or dispersion of a set of data is often just as important as its central tendency. This variability can be quantified by measures known as the *range* and the *standard deviation*.

As described in the chapter on research in psychology, the **range** is simply the difference between the highest and the lowest values in a data set. For the data in Table 1, the range for the low-incentive group is $9 - 2 = 7$; for the high-incentive group, the range is $10 - 3 = 7$.

The **standard deviation**, or **SD**, measures the average difference between each score and the mean of the data set. To see how the standard deviation is calculated, consider the data in Table 2. The first step is to compute the mean of the set—in this case, $20/5 = 4$. Second, calculate the difference, or *deviation* (D), of each score from the mean by subtracting the mean from each score, as in column 2 of Table 2. Third, find the average of these deviations. Notice, though, that if you calculated this average by finding the arithmetic mean, you would sum the deviations and find that the negative deviations

TABLE 2 Calculating the Standard Deviation

The standard deviation of a set of scores reflects the average degree to which those scores differ from the mean of the set.

Raw Data	Difference from Mean = D	D^2
2	$2 - 4 = -2$	4
2	$2 - 4 = -2$	4
3	$3 - 4 = -1$	1
4	$4 - 4 = 0$	0
9	$9 - 4 = 5$	25
Mean = $20/5 = 4$		$\Sigma D^2 = 34$
Standard deviation = $\sqrt{\frac{\Sigma D^2}{N}} = \sqrt{\frac{34}{5}} = \sqrt{6.8} = 2.6$		

Note: Σ means "the sum of."

exactly balance the positive ones, resulting in a mean difference of 0. Obviously there is more than zero variation around the mean in the data set. So, instead of employing the arithmetic mean, you compute the standard deviation by first squaring the deviations (which, as shown in column 3 of Table 2, removes any negative values). You then add up these squared deviations, divide the total by *N*, and then take the square root of the result.

The Normal Distribution

Now that we have described histograms and reviewed some descriptive statistics, let's reexamine how these methods of representing research data relate to some of the concepts discussed elsewhere in the book.

In most subfields in psychology, when researchers collect many measurements and plot their data in histograms, the resulting pattern often resembles the one shown for the low-incentive group in Figure 1. That is, the majority of scores tend to fall in the middle of the distribution, with fewer and fewer scores occurring as one moves toward the extremes. As more and more data are collected, and as smaller and smaller bins are used (perhaps containing only one value each), histograms tend to smooth out until they resemble the bell-shaped curve known as the **normal distribution**, or *normal curve*. When a distribution of scores follows a truly normal curve, its mean, median, and mode all have the same value. Furthermore, if the curve is normal, we can use its standard deviation to describe how any particular score stands in relation to the rest of the distribution.

IQ scores provide an example. They are distributed in a normal curve, with a mean, median, and mode of 100 and an SD of 16—as shown in Figure 2. In such a distribution, half of the population will have an IQ above 100, and half will be below 100. The shape of the true normal curve is such that 68 percent of the area under it lies in a range within one standard deviation above and below the mean. In terms of IQ, this means that 68 percent of the population has an IQ somewhere between 84 (100 minus 16) and 116 (100 plus 16). Of the remaining 32 percent of the population, half falls more than 1 SD above the mean, and half falls more than 1 SD below the mean. Thus, 16 percent of the population has an IQ above 116, and 16 percent scores below 84.

The normal curve is also the basis for percentiles. A **percentile** indicates the percentage of people or observations that fall below a given score in a normal distribution. In Figure 2, for example, the mean score (which is also the median) lies at a point below which 50 percent of the scores fall. Thus the mean of a normal distribution is at the

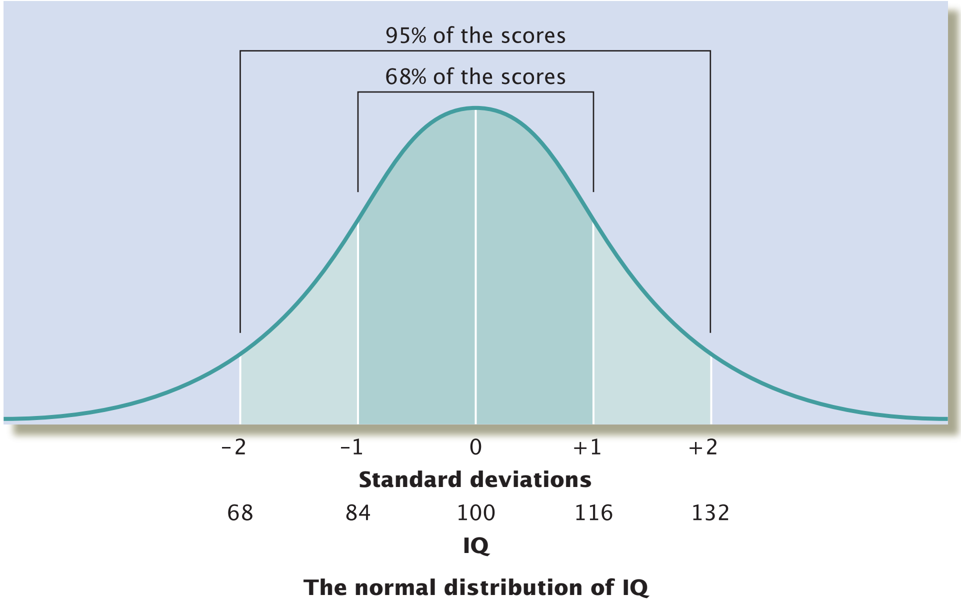
normal distribution A dispersion of scores such that the mean, median, and mode all have the same value.

percentile A value that indicates the percentage of people or observations that fall below a given point in a normal distribution.

FIGURE 2

The Normal Distribution

Many kinds of research data approximate the balanced, or symmetrical, shape of the normal curve, in which most scores fall toward the center of the range.



50th percentile. What does this say about IQ? If you score 1 SD above the mean, your score is at a point above which only 16 percent of the population falls. This means that 84 percent of the population (100 percent minus 16 percent) must be below that score; so this IQ score is at the 84th percentile. A score at 2 SDs above the mean is at the 97.5 percentile, because only 2.5 percent of the scores are above it in a normal distribution.

Scores may also be expressed in terms of their distance in standard deviations from the mean, producing what are called **standard scores.** A standard score of 1.5, for example, is 1.5 standard deviations from the mean.

Correlation Histograms and measures of central tendency and variability describe certain characteristics of one dependent variable at a time. However, psychologists are often interested in describing the relationship between two variables. Measures of correlation are frequently used for this purpose. We discussed the interpretation of the *correlation coefficient* in the chapter on research in psychology; here we describe how to calculate it.

Recall that correlations are based on the relationship between two numbers that are associated with each participant or observation. The numbers might represent, say, a person's height and weight or the IQ scores of a parent and child. Table 3 contains this kind of data for four participants from our incentives study who took the test twice. (As you may recall from the chapter on cognitive abilities, the correlation between their scores would be a measure of test-retest reliability.)

The formula for computing the Pearson product-moment correlation, or *r*, is as follows:

$$r = \frac{\Sigma(x - M_x)\,(y - M_y)}{\sqrt{\Sigma(x - M_x)^2\,\Sigma(y - M_y)^2}}$$

where:

x = each score on variable 1 (in this case, test 1)
y = each score on variable 2 (in this case, test 2)
M_x = the mean of the scores on variable 1
M_y = the mean of the scores on variable 2

The main function of the denominator (bottom part) in this formula is to ensure that the coefficient ranges from +1.00 to −1.00, no matter how large or small the values of the variables being correlated. The "action element" of this formula is the numerator (or top part). It is the result of multiplying the amounts by which each of two observations (x and y) differ from the means of their respective distributions (M_x and M_y). Notice that, if the two variables "go together" (so that, if one score is large, the score it is

TABLE 3 Calculating the Correlation Coefficient

Though it appears complex, calculation of the correlation coefficient is quite simple. The resulting *r* reflects the degree to which two sets of scores tend to be related, or to co-vary.

Participant	Test 1	Test 2	$(x - M_x)(y - M_y)^{(b)}$
A	1	3	$(1 - 3)(3 - 4) = (-2)(-1) = +2$
B	1	3	$(1 - 3)(3 - 4) = (-2)(-1) = +2$
C	4	5	$(4 - 3)(5 - 4) = (1)(1) = +1$
D	6	5	$(6 - 3)(5 - 4) = (3)(1) = +3$
	$^{(a)}M_x = 3$	$M_y = 4$	$\Sigma(x - M_x)(y - M_y) = +8$
$^{(c)}\Sigma(x - M_x)^2 = 4 + 4 + 1 + 9 = 18$			
$^{(d)}\Sigma(y - M_y)^2 = 1 + 1 + 1 + 1 = 4$			
$^{(e)}r = \frac{\Sigma(x - M_x)\,(y - M_y)}{\sqrt{\Sigma(x - M_x)^2\,\Sigma(y - M_y)^2}} = \frac{8}{\sqrt{18 \times 4}} = \frac{8}{\sqrt{72}} = \frac{8}{8.48} = +.94$			

standard scores Values that indicate the distance, in standard deviations, between a given score and the mean of all the scores in a data set.

paired with is also large, and if one is small, the other is also small), then both scores in each pair will tend to be above the mean of their distribution or both of them will tend to be below the mean of their distribution. When this is the case, $x - M_x$ and $y - M_y$ will both be positive, or they will both be negative. In either case, when you multiply one of them by the other, their product will always be positive, and the correlation coefficient will also be positive. If, on the other hand, the two variables go opposite to one another, such that, when one score in a pair is large, the other is small, one of them is likely to be smaller than the mean of its distribution, so that either $x - M_x$ or $y - M_y$ will have a negative sign, and the other will have a positive sign. Multiplying these differences together will always result in a product with a negative sign, and r will be negative as well.

TRY THIS

Now compute the correlation coefficient for the data presented in Table 3. The first step (step *a* in the table) is to compute the mean (M) for each variable. M_x turns out to be 3 and M_y is 4. Next, calculate the numerator by finding the differences between each x and y value and its respective mean and by multiplying them (as in step *b* of Table 3). Notice that, in this example, the differences in each pair have like signs, so the correlation coefficient will be positive. The next step is to calculate the terms in the denominator; in this case, as shown in steps *c* and *d* in Table 3, they have values of 18 and 4. Finally, place all the terms in the formula and carry out the arithmetic (step *e*). The result in this case is an r of $+.94$, a high and positive correlation suggesting that performances on repeated tests are very closely related. A participant doing well the first time is very likely to do well again; a person doing poorly at first will probably do no better the second time.

Inferential Statistics

The descriptive statistics from the incentives experiment tell the experimenter that the performances of the high- and low-incentive groups differ. But there is some uncertainty. Is the difference large enough to be important? Does it represent a stable effect or a fluke? The researcher would like to have some *measure of confidence* that the difference between groups is genuine and reflects the effect of incentives on mental tasks in the real world, rather than the effect of random or uncontrolled factors. One way of determining confidence would be to run the experiment again with a new group of participants. Confidence that incentives produced differences in performance would grow stronger if the same or a larger between-group difference occurs again. In reality, psychologists rarely have the opportunity to repeat, or *replicate*, their experiments in exactly the same way three or four times. But **inferential statistics** provide a measure of how likely it was that results came about by chance. They put a precise mathematical value on the confidence or probability that rerunning the same experiment would yield similar (or even stronger) results.

Differences Between Means: The *t* Test

One of the most important tools of inferential statistics is the t test. It allows the researcher to ask how likely it is that the difference between two means occurred by chance rather than as a function of the effect of the independent variable. When the t test or other inferential statistic says that the probability of chance effects is small enough (usually less than 5 percent), the results are said to be *statistically significant*. Conducting a t test of statistical significance requires the use of three descriptive statistics.

The first component of the t test is the size of the observed effect, the difference between the means. Recall that the mean is calculated by summing a group's scores and dividing that total by the number of scores. In the example shown in Table 1, the mean of the high-incentive group is 94/13, or 7.23, and the mean of the low-incentive group is 65/13, or 5. So the difference between the means of the high- and low-incentive groups is $7.23 - 5 = 2.23$.

Second, we have to know the standard deviation of scores in each group. If the scores in a group are quite variable, the standard deviation will be large, indicating that chance may have played a large role in producing the results. The next replication of

inferential statistics A set of procedures that provides a measure of how likely it is that research results came about by chance.

the study might generate a very different set of group scores. If the scores in a group are all very similar, however, the standard deviation will be small, which suggests that the same result would probably occur for that group if the study were repeated. In other words, the *difference* between groups is more likely to be significant when each group's standard deviation is small. If variability is high enough that the scores of two groups overlap, the mean difference, though large, may not be statistically significant. (In Table 1, for example, some people in the low-incentive group actually did better on the math test than some in the high-incentive group.)

Third, we need to take the sample size, *N*, into account. The larger the number of participants or observations, the more likely it is that an observed difference between means is significant. This is so because, with larger samples, random factors within a group—the unusual performance of a few people who were sleepy or anxious or hostile, for example—are more likely to be canceled out by the majority, who better represent people in general. The same effect of sample size can be seen in coin tossing. If you toss a quarter five times, you might not be too surprised if heads comes up 80 percent of the time. If you get 80 percent heads after one hundred tosses, however, you might begin to suspect that this is probably not due to chance alone and that some other effect, perhaps some bias in the coin, is significant in producing the results. (For the same reason, even a relatively small correlation coefficient—between diet and grades, say—might be statistically significant if it was based on 50,000 students. As the number of participants increases, it becomes less likely that the correlation reflects the influence of a few oddball cases.)

To summarize, as the differences between the means get larger, as *N* increases, and as standard deviations get smaller, *t* increases. This increase in *t* raises the researcher's confidence in the significance of the difference between means.

Let's now calculate the *t* statistic and see how it is interpreted. The formula for *t* is:

$$t = \frac{(M_1 - M_2)}{\sqrt{\frac{(N_1 - 1)S_1^2 + (N_2 - 1)\,S_2^2}{N_1 + N_2 - 2}\left(\frac{N_1 + N_2}{N_1 N_2}\right)}}$$

where:

M_1 = mean of group 1
M_2 = mean of group 2
N_1 = number of scores or observations for group 1
N_2 = number of scores or observations for group 2
S_1 = standard deviation of group 1 scores
S_2 = standard deviation of group 2 scores

Despite appearances, this formula is quite simple. In the numerator is the difference between the two group means; *t* will get larger as this difference gets larger. The denominator contains an estimate of the standard deviation of the *differences* between group means; in other words, it suggests how much the difference between group means would vary if the experiment were repeated many times. Because this estimate is in the denominator, the value of *t* will get smaller as the standard deviation of group differences gets larger. For the data in Table 1,

$$\begin{aligned} t &= \frac{(M_1 - M_2)}{\sqrt{\frac{(N_1 - 1)S_1^2 + (N_2 - 1)S_2^2}{N_1 + \mathrm{N}_2 - 2}\left(\frac{N_1 + N_2}{N_1 N_2}\right)}} \\ &= \frac{7.23 - 5}{\sqrt{\frac{(12)(5.09) + (12)(4.46)}{24}\left(\frac{26}{169}\right)}} \\ &= \frac{2.23}{\sqrt{.735}} = 2.60 \text{ with 24 df} \end{aligned}$$

To determine what a particular *t* means, we must use the value of *N* and a special statistical table called, appropriately enough, the *t table*. We have reproduced part of the *t* table in Table 4.

TABLE 4 The *t* Table

This table allows the researcher to determine whether an obtained *t* value is statistically significant. If the *t* value is larger than the one in the appropriate row in the .05 column, the difference between means that generated that *t* score is usually considered statistically significant.

	***p* Value**		
df	.10 (10%)	.05 (5%)	.01 (1%)
4	1.53	2.13	3.75
9	1.38	1.83	2.82
14	1.34	1.76	2.62
19	1.33	1.73	2.54
22	1.32	1.71	2.50
24	1.32	1.71	2.49

First, we have to find the computed values of *t* in the row corresponding to the **degrees of freedom,** or **df**, associated with the experiment. In this case, degrees of freedom are simply $N_1 + N_2 - 2$ (or two less than the total sample size or number of scores). Because our experiment had 13 participants per group, df $= 13 + 13 - 2 = 24$. In the row for 24 df in Table 4, you will find increasing values of *t* in each column. These columns correspond to decreasing *p* values, the probabilities that the difference between means occurred by chance. If an obtained *t* value is equal to or larger than one of the values in the *t* table (on the correct df line), then the difference between means that generated that *t* is said to be significant at the .10, .05, or .01 level of probability.

Suppose, for example, that an obtained *t* (with 19 df) was 2.00. Looking along the 19 df row, you find that 2.00 is larger than the value in the .05 column. This allows you to say that the probability that the difference between means occurred by chance was no greater than .05, or 5 in 100. If the *t* had been less than the value in the .05 column, the probability of a chance result would have been greater than .05. As noted earlier, when an obtained *t* is not large enough to exceed *t* table values at the .05 level, at least, it is not usually considered statistically significant. The *t* value from our experiment was 2.60, with 24 df. Because 2.60 is greater than all the values in the 24 df row, the difference between the high- and low-incentive groups would have occurred by chance less than 1 time in 100. In other words, the difference is statistically significant.

Beyond the *t* Test

Many experiments in psychology are considerably more complex than simple comparisons between two groups. They often involve three or more experimental and control groups. Some experiments also include more than one independent variable. For example, suppose we had been interested not only in the effect of incentive size on performance but also in the effect of problem difficulty. We might then create six groups whose members would perform easy, moderate, or difficult problems and would receive either low or high incentives.

In an experiment like this, the results might be due to the size of the incentive, the difficulty of the problems, or the combined effects (known as the *interaction*) of the two. Analyzing the size and source of these effects is typically accomplished through procedures known as *analysis of variance*. The details of analysis of variance are beyond the scope of this book. For now, note that the statistical significance of each effect is influenced by the size of the differences between means, by standard deviations, and by sample size in much the same way as we described for the *t* test. For more detailed information about how analysis of variance and other inferential statistics are used to understand and interpret the results of psychological research, consider taking courses in research methods and statistical or quantitative methods.

degrees of freedom (df) The total sample size or number of scores in a data set, less the number of experimental groups.

SUMMARY

Psychological research generates large quantities of data. Statistics are methods for describing and drawing conclusions from data.

Describing Data

Researchers often use *null hypothesis testing* to evaluate the assertion that the independent variable will have no effect on the dependent variable.

The Histogram

Graphic representations such as *histograms* provide visual descriptions of data, making the data easier to understand.

Descriptive Statistics

Numbers that summarize a set of data are called *descriptive statistics*. The easiest statistic to compute is *N*, which gives the number of observations made. A set of scores can be described by two other types of descriptive statistics: a measure of central tendency, which describes the typical value of a set of data, and a measure of variability. Measures of central tendency include the mean, median, and mode; variability is typically measured by the *range* and by the *standard deviation*. Sets of data often follow a *normal distribution*, which means that most scores fall in the middle of the range, with fewer and fewer scores occurring as one moves toward the extremes. In a truly normal distribution the mean, median, and mode are identical. When a set of data shows a normal distribution, a data point can be cited in terms of a *percentile*, which indicates the percentage of people or observations falling below a certain score, and in terms of *standard scores*, which indicate the distance, in standard deviations, between any score and the mean of the distribution. Another type of descriptive statistic, a correlation coefficient, is used to measure the correlation between sets of scores.

Inferential Statistics

Researchers use *inferential statistics* to quantify the probability that conducting the same experiment again would yield similar results.

Differences Between Means: The *t* Test

One inferential statistic, the *t* test, assesses the likelihood that differences between two means occurred by chance or reflect the impact of an independent variable. Performing a *t* test requires using the difference between the means of two sets of data, the standard deviation of scores in each set, and the number of observations or participants. Interpreting a *t* test requires that *degrees of freedom* also be taken into account. When the *t* test indicates that the experimental results had a low probability of occurring by chance, the results are said to be statistically significant.

Beyond the *t* Test

When more than two groups must be compared, researchers typically rely on analysis of variance in order to interpret the results of an experiment.

SUBJECT INDEX/GLOSSARY

Key terms, which appear in ***boldface****, are followed by their definitions.*
Entries that appear in blue refer to the Neuropsychology or Industrial/Organizational Psychology chapters or the online-only Appendices B and C.

AA. *See* Affirmative action
Abecedarian Project, 389
Abilify, 683, 686
Abnormal behavior, 598–599
Absenteeism, 525, 791
Absolute pitch *The ability to identify the musical notes associated with specific sound frequencies,* 114
Absolute threshold *The minimum amount of stimulus energy that can be detected 50 percent of the time,* 160–161, 193
Abuse. *See* Child abuse
Accessory structures *Structures, such as the lens of the eye, that modify a stimulus,* 110–111
  auditory, 115, 120
  olfactory, 136
  visual, 121, 135
Accidental reinforcement, 216
Accidents, workplace, 795
Accommodation *The process of modifying schemas when familiar schemas do not work,* 474
Acetylcholine *A neurotransmitter used by neurons in the peripheral and central nervous systems in the control of functions ranging from muscle contraction and heart rate to digestion and memory,* 99, 102, 272, 362, 448, 827
Achievement measures *Tests designed to measure what a person has accomplished or learned in a particular area,* 378
Achievement motivation *The degree to which a person establishes specific goals, cares about meeting those goals, and experiences feelings of satisfaction by doing so,* 436
  assessment of, 437
  development of, 437–438
  goal setting and, 438
  individual differences, 436–437
  well-being and, 440–441
  workplace and, 439–440
Acoustic encoding, 242, 250
Acoustic nerve *The bundle of axons that carries stimuli from the hair cells of the cochlea to the brain,* 115
Acquired immune deficiency syndrome (AIDS), 312, 432, 539, 540, 544–545, 792–793
Acquisition, in classical conditioning, 202, 207
Acrophobia, 610
ACT. *See* American College Testing Assessment
ACTH. *See* Adrenocorticotropic hormone
Action potential *An abrupt wave of electrochemical changes traveling down an axon when a neuron becomes depolarized,* 67, 105
Action tendency, 445
Activation-synthesis theory, 350
Active learning, 233–234, 237
Active listening (reflection) *Conveying empathy on the part of the therapist by paraphrasing a client's statements and noting accompanying feelings,* 657
Actor-observer effect *The tendency to attribute other people's behavior to internal causes while attributing our own behavior (especially errors and failures) to external causes,* 706–707
Actual criterion, for job performance, 774–775
Actualizing tendency *According to Carl Rogers, an innate inclination toward growth that motivates all people,* 578
Acupuncture, 75, 147–149
Adaptation
  to changing environments, 196
  learning and, 197, 198
  sensory systems, 110, 110–111
Addiction *Development of a physical need for a psychoactive drug,* 356
  dependence and, 356–357, 641–643
  opponent-process theory, 444
  research on, 79
Additive color mixing, 129
A-delta fibers, 143–144
ADHD. *See* Attention deficit hyperactivity disorder
Adolescence
  body, changes in, 500–501
  brain, changes in, 500–501
  cognitive development in, 500–501, 504
  emerging adulthood, 508
  ethnic identity, 505
  feelings and behavior, 501–502
  identity in, 505–506
  love and sex, 502–504
  moral development, 506–508
  parenting and, 503–504
  puberty and, 500–501, 516
  sexual activity in, 502–503
  sleep patterns in, 342–343
  suicide in, 501
  violent behavior in, 504
Adoption studies
  behavioral genetics, 50, A7, A10
  IQ and, 385, 387–388
  schizophrenia and, A10
Adrenal cortex, 103, 544
Adrenal glands, 104, 529, 549
Adrenal medulla, 103, 448
Adrenaline, 100, 448, 528–529
Adrenocorticotropic hormone (ACTH), 104, 529
Adulthood. *See also* Late adulthood
  career choice, 512
  cognitive changes, 509–511
  death and dying, 516–517
  developmental trajectories, 517
  emerging, 508
  identity crisis, 508–509
  longevity, 517–518
  physical changes, 509
  social changes, 512–516
Affective disorder (mood disorder) *A condition in which a person experiences extreme moods, such as depression or mania,* 620
  bipolar disorders, 623–625
  causes of, 624–627
  depressive disorders, 620–623
Afferent neurons, 73
Affirmative action (AA), 780
Afterimages, 132
Age regression, 351
Age-graded test items, 374
Aggression *An act that is intended to cause harm to another person,* 743
  in adolescence, 504
  alcohol and, 744–745
  arousal and, 749–750
  biological factors in, 743–745
  circumstances for, 748–750
  cognitive factors in, 21
  correlational studies in, 41
  crowding and, 750
  cultural factors in, 745–746
  defensive, 744
  emotional factors in, 750
  environmental influences on, 750
  frustration and, 748–749
  gender differences in, 497
  generalized arousal and, 749–750
  genetics factors in, 743–745
  instrumental, 792
  observational learning and, 228–229
  pornography and, 41, 749
  punishment and, 218

Aggression (*continued*)
  reasons for, 743–746
  serotonin and, 100
  stress and, 527, 532
  television and, 230
  temperature and, 750
  testosterone and, 744–745
  trait theory, 566
  video games and, 746–748
  in workplace, 791–792
Agonist *A drug that mimics the effects of the neurotransmitter that normally binds to a neural receptor,* 355–356
Agoraphobia *An anxiety disorder involving strong fear of being alone or away from the security of home,* 611, 660
Agrammatism, 823
Agranulocytosis, 683
Agreeableness, 567, 763, 790, 797
AI. *See* Artificial intelligence
AIDS. *See* Acquired immune deficiency syndrome
Alarm reaction, 528
Alcohol
  aggression and, 744–745
  cerebellum and, 82
  as depressant, 358–359, 365
  expectations and, 357
  GABA receptors and, 358
  medications and, 684–686
  memory and, 257, 275, 358–359
  prenatal risks and, 358, 469
  sleeping pills and, 346
  stress and, 532, 536, 551
  in substance-related disorder, 641–642
Alcohol abuse, 641
Alcohol dependence, 641
Alcoholism *A pattern of drinking that may lead to addiction and almost always causes severe social, physical, and other problems,* 641–642
Alexia without agraphia, 808–809
Algorithm *A systematic procedure that cannot fail to produce a correct solution to a problem if a solution exists,* 295
All-or-none law, 67
All-or-none thinking, 666
Allport's trait theory, 566–567
Alpha waves, 340
Alprazolam, 685
Altered state of consciousness *A condition in which changes in mental processes are extensive enough that a person or others notice significant differences in psychological and behavioral functioning,* 339
Altruism *An unselfish concern for another person's welfare,* 751
  family and, 756–758
  reasons for, 752–756
Alzheimer's disease, 511
  background of, 84–86
  brain and, 84, 827
  chemistry of, 99
  dementia and, 84, 826–828
  diagnosis of, 85
  gender and, 511
  genetic factors in, A9
  memory and, 84, 272
  research on, 85–86
  treatment of, 86
Ambiguity, conformity and, 735, 742
Ambivalent attachment, 488
American College Testing Assessment (ACT), 378
American Sign Language (ASL), 118, 251, 323
Amitid, 686
Amnesia
  anterograde, 12, 83, 273–275, 338, 712, 815
  disorders and, 813–816
  dissociative, 618
  infantile, 480
  post-hypnotic, 480
  retrograde, 274
Amnestic disorders *Neuropsychological disorders that involve memory loss,* 813–816
Amnestic MCI, 826
Amphetamines, 360, 365, 745
Amplitude *The difference between the peak and the baseline of a waveform,* 113–114, 120, 340
Amygdala *A structure in the forebrain that, among other things, associates features of stimuli from two sensory modalities,* 82–83, 98
  aggression and, 744
  emotion and, 432, 446–447, 453
  prejudice and, 714
Amyloid plaque, 827
Amyloid precursor protein, 84
Anafranil, 685, 690
Anal stage *The second of Freud's psychosexual stages of personality development, usually occurring during the second year of life, in which the focus of pleasure and conflict shifts from the mouth to the anus,* 560
Analgesia *The absence of pain sensations in the presence of a normally painful stimulus,* 146
Analgesics, natural, 146–147
Analogical mapping, 302–303
Analogical representations, 294
Analogies, 77, 301–301
Analogue studies, 756
Analysis of variance, A19
Analytic psychology, 561–562
Analytical intelligence, 396
Anchoring heuristic (anchoring bias) *A mental shortcut that involves basing judgments on existing information,* 298–299
Androgens *Sex hormones that circulate in the bloodstream in both sexes; more androgens circulate in men than in women,* 103, 430–431
Anger
  aggression and, 414
  alcohol and, 359
  emotional expression of, 445, 447, 451, 456, 458–459
Animal Welfare Act, 58
Animals
  language and, 322–325
  personalities and, 568
  in research, 57–58
Animism, 475
Anomia, 827
Anorexia nervosa *An eating disorder characterized by self-starvation and dramatic weight loss,* 427
Anosmia, 140
Anosognosia, 817–819, 829
ANS. *See* Automatic nervous system
Antagonist *A drug that binds to a receptor and prevents the normal neurotransmitter from binding,* 355–356, 360, 361, 363, 690
Anterior cingulate cortex, 143, 144
Anterograde amnesia *A loss of memory for any event that occurs after a brain injury,* 12, 83, 273–275, 338, 712, 815
Antianxiety drugs, 685–686. *See also* Anxiolytics
Antibodies, 544
Anticonvulsants, 684–685
Antidepressant drugs *Medications that relieve depression,* 100, 428, 684–688, 690
Antipsychotics, 683, 686
Antisocial behavior, A9
Antisocial personality disorder (APD) *A personality disorder involving impulsive, selfish, unscrupulous, and even criminal behavior,* 635
Anvil, in ear structure, 115
Anxiety
  anxiolytics and, 685–687
  behavior therapy for, 659–667
  in childhood, 486, 493, 639
  depression and, 606
  EMDR and, 31, 33–36, 43
  genetic factors in, A9
  interpersonal psychotherapy for, 689
  meditation and, 354
  motivational conflicts and, 444
  self-esteem and, 699–700

  regulation of, 444
  sexual, 429, 432
  stress and, 531, 534, 538
Arousal: cost-reward theory *A theory attributing people's helping behavior to their efforts to reduce the unpleasant arousal they feel in the face of someone's need or suffering,* 752–754
Arousal theory *A theory of motivation stating that people are motivated to behave in ways that maintain what is for them an optimal level of arousal,* 418
Arousal-performance relationship, 419
Arteries, 812
Arthritis, 45
Artificial intelligence (AI) *The field that studies how to program computers to imitate the products of human perception, understanding, and thought,* 23, 308
ASD. *See* Autistic spectrum disorders
ASL. *See* American Sign Language
Asperger's syndrome, 640
Assertiveness training *A form of social skills training that focuses on teaching clients to express themselves in ways that are clear and direct,* 662
Assessment center *An extensive set of exercises designed to determine an individual's suitability for a particular job,* 773–774
Assimilation *The process of trying out existing schemas on objects that fit those schemas,* 474
Association cortex *The parts of the cerebral cortex that receive information from more than one sense or that combine sensory and motor information to perform complex cognitive tasks,* 89–91
Associations
  learning and, 200–207
  memory and, 247, 258–260
  neural networks and, 221–222
Associative networks, 221
Astringent, 139
Ataques de nervios, 601, 618
Attachment *A deep and enduring relationship with a caregiver or other person with whom a baby has shared many early experiences,* 486–488, 512
  day care and, 487–490
  object relations and, 563, 656
Attachment behavior *Actions such as crying, smiling, vocalizing, and gesturing that help bring an infant into closer proximity to its caregiver,* 487
Attachment theory *The idea that children form a close attachment to their earliest caregivers and that this attachment pattern can affect aspects of the children's later life,* 486, 563
Attention deficit hyperactivity disorder (ADHD), 639
Attention *The process of directing and focusing psychological resources to enhance perception, performance, and mental experience,* 184–185, 194
  aging and, 402, 510
  automatic processing and, 189, 194
  brain and, 189, 194

  stress and, 528–529, 544, 613
  vestibular sense and, 150–151
Autonomic reactivity, 546–547
Autonomous work groups (AWGs) *Self-managed employee groups that do not report to anyone for routine daily supervision,* 796–797
Availability heuristic *A mental shortcut in which judgments are based on information that is most easily brought to mind,* 299–300
Aversion conditioning *A method that uses classical conditioning to create a negative response to a particular stimulus,* 664, 665
Aversion therapy, 664
Aversive racism, 718
Aversively stimulated aggression theory, 748–749
Aviation psychology, 189–190, 194
Avoidance conditioning *A type of learning in which an organism responds to a signal in a way that prevents exposure to an aversive stimulus,* 209–211, 221
Avoidance-avoidance conflicts, 443
Avoidant attachment, 488
Avoidant personality disorder, 634
AWGs. *See* Autonomous work groups
Axes, 604–605
Axons *Fibers that carry signals from the body of a neuron out to where communication occurs with other neurons,* 66, 105–106

Big Five traits, 763
Bilingualism, 321–322
Binocular disparity, 172–173
Biofeedback training, 334
Biological approach *An approach to psychology in which behavior and behavior disorders are seen as the result of physical processes, especially those relating to the brain and to hormones and other chemicals,* 19
Biological clock, 344, 514, 625
Biological preparedness, 615
Biological psychologists *Psychologists who analyze the biological factors influencing behavior and mental processes. Also called physiological psychologists,* 4
Biological psychology *The psychological specialty focused on the physical and chemical changes that cause, and occur in response to, behavior and mental processes,* 5, 63–64
Biological trait theory, 568–570
Biological treatments
  drugs and psychotherapy, 688–690
  EST, 682
  psychoactive drugs, 683–688
  psychosurgery, 682
Biopreparedness, 205, 716
Biopsychosocial approach *A view of mental disorders as caused by a combination of interacting biological, psychological, and sociocultural factors,* 599, 599–603
Bipolar cells, 124
Bipolar disorders *Affective disorders in which a person alternates between the emotional extremes of depression and mania,* 623–625
Bisexuality *Sexual motivation that is focused on members of both sexes,* 433
Blind spot *The light-insensitive point at which axons from all of the ganglion cells converge and exit the eyeball,* 126–127
Blindness, 616, 653, 817
Blindness, hypnosis and, 353
Blindness, inattentional, 187–188, 192
Blindsight, 335
Blood pressure, 72, 80, 206, 340, 354, 447, 449, 545–546
Blood-brain barrier *A feature of blood vessels supplying the brain that allows only certain substances to leave the blood and interact with brain tissue,* 355
BMI. *See* Body mass index
BnST. *See* Bed nucleus of the stria terminalis

Body dysmorphic disorder *A somatoform disorder characterized by intense distress over imagined abnormalities of the skin, hair, face, or other areas of the body,* 617
Body language, 659
Body mass index (BMI), 425
Body-kinesthetic intelligence, 398

  prejudice and, 715–716
  stress and, 530–532

Cognitive Abilities Test, 382
Cognitive ability *The capacity to reason, remember, understand, solve problems, and make decisions,* 373–374
  achievement measures, 378–379
  aging and, 400–402
  aptitude measures, 378–379
  diversity in, 402–407
  emotionality and, 383–384
  intelligence, 393–399
  intelligence tests, 374–378, 381–383, 391–393
  IQ tests and, 384–391
  late adulthood and, 510–511
  statistical reliability, 379–380
  statistical validity, 380–381
Cognitive appraisal theory, 454
Cognitive approach *A way of looking at human behavior that emphasizes research on how the brain takes in information, creates perceptions, forms and retrieves memories, processes information, and generates integrated patterns of action,* 22
  to learning, 222–229, 237
  to psychology, 22
Cognitive behavior therapists, 665
Cognitive behavior therapy *Learning-based treatment methods that help clients change the way they think, as well as the way they behave,* 665
  cognitive therapy, 666–667
  REBT, 665–666
Cognitive coping strategies, 550–551
Cognitive development
  brain and, 472
  building blocks of, 473–474
  concrete operations, 476
  culture and, 481–482
  endangering, 482–484
  formal operational stage, 476
  improving, 482–484
  infants, new views of, 477–478
  information processing, 478–480
  knowledge development, 472–473
  memory and, 480–481
  Piaget's theory, 472–478
  preoperational stage, 475–476
  sensorimotor stage, 474–475
  stages of, 478
Cognitive dissonance theory *A theory asserting that attitude change is driven by efforts to reduce tension caused by inconsistencies between attitudes and behaviors,* 711–712
Cognitive distortions, 666
Cognitive interpretation, 454
Cognitive map *A mental representation of the environment,* 225–226, 237, 294–295
Cognitive neuroscience, 285, 332
Cognitive person variables, 575
Cognitive psychologists *Psychologists who study the mental processes underlying judgment, decision making, problem solving, imagining, and other aspects of human thought or cognition. Also called experimental psychologists,* 5
Cognitive psychology *The study of the mental processes by which information from the environment is modified, made meaningful, stored, retrieved, used, and communicated to others,* 6
Cognitive restructuring, 551, 666
Cognitive science, 23, 332
Cognitive therapy *A treatment in which the therapist helps clients notice and change negative thoughts associated with anxiety and depression,* 666–667
Cognitive unconscious, 334
Cognitive-affective theory, 575–576
Cognitive-behavioral approach, 21–22
Cognitively disabled, 405–406
Collective unconscious, 562
Collectivist cultures, 25–26
  dissonance and, 712
  fundamental attribution error and, 706
  interpersonal conflict and, 761
  moral reasoning and, 506
  parenting styles and, 492
  personality and, 582–583
  psychotherapy and, 678
  self-esteem and, 699
  social striving and, 732
Color circle, 130
Color coding, 132
Color saturation *The purity of a color,* 129
Color vision, 129
  opponent-process theory, 131–132
  synthesis of, 132–133
  trichromatic theory of, 129–131
  wavelengths and, 129
Colorblindness *A condition in which lack of certain photopigments leave a person unable to sense certain colors,* 133–134
Coma, 816
Commitment, in intimate relationships, 722, 723
Common fate, in perceptual grouping, 168
Common region, in perceptual grouping, 169
Commons dilemma, 760
Communication. *See also* Language
  facilitated, 55–57
  gender and styles of, 26–27
  marriage and, 724
Community mental health movement, 690–691
Community psychologists *Psychologists who work to obtain psychological services for people in need of help and to prevent psychological disorders by working for changes in social systems,* 7
Community psychology, 6–7
Community psychology *A movement to minimize or prevent psychological disorders through changes in social systems and through community mental health programs,* 7, 690–691
Comorbidity, 596
Companionate love, 722
Compensation, 560
Competition *Behavior in which individuals try to attain a goal for themselves while denying that goal to others,* 758
Complementarity concept, 476
Complementary colors, 132
Compliance *Adjusting one's behavior because of an explicit or implicit request,* 732–733
  creating, 736–737
  norms and, 733–734
Compulsions *Repetitive behaviors that interfere with daily functioning but are performed in an effort to prevent dangers or events associated with obsessions,* 612
Computational model *An approach to perception that focuses on how computations by the nervous system translate raw sensory stimulation into an experience of reality,* 158–159
Computational neuroscientists, 72
Computational theory of the mind, 23
Computers, 18, 23
  human interaction with, 190–191
  modeling of brain by, 72
  perceptual tasks and, 181
  problem solving, 308–309
Concept *A category of objects, events, or ideas that have common properties,* 291–292, 296
Conceptual act model, 455
Concrete operations *According to Piaget, the third stage of cognitive development, during which children's thinking is no longer dominated by visual appearances,* 476
Concussion, 274
Conditioned reinforcers, 213
Conditioned response (CR) *The response that the conditioned stimulus elicits,* 202–203, 207, 223
Conditioned stimulus (CS) *The originally neutral stimulus that, through pairing with the unconditioned stimulus, comes to elicit a conditioned response,* 202–203, 205–207
Conditioning. *See* Classical conditioning; Operant conditioning
Conditions of worth, 657
Conduct disorders, 638
Conduction deafness, 115
Cones *Photoreceptors in the retina that help us distinguish colors,* 123–124, 125, 131–133, 135

Confabulation *A characteristic of some neuropsychological disorders in which patients report false memories,* 815
Confirmation bias *The tendency to pay more attention to evidence in support of one's hypothesis than to evidence that refutes that hypothesis,* 297, 305–306
Conflict *The result of a person's or group's belief that another person or group stands in the way of their achieving a valued goal,* 758
  interpersonal, 761–762
  managing, 762
  motivational, 443–444
  personality structure, psychodynamic approach to, 559–560
  unconscious, 559, 600, 603, 654
  work-family, 787–788
Conformity *Changing one's behavior or beliefs to match those of others, generally as a result of real or imagined, though unspoken, group pressure,* 732–733
  circumstances for, 734–736
  norms and, 733–734
  reasons for, 734
Confound *In an experiment, any factor that affects the dependent variable, along with or instead of the independent variable,* 43
Congruence *Consistency between a therapist's feelings and the therapist's behavior toward clients,* 658–659
Connectedness, in perceptual grouping, 169
Connectionist models, 181, 222, 309. *See also* Neural network models
Conscientiousness, 542, 567, 772
Conscious level *The level at which mental activities that people are normally aware of occur,* 333–334
Consciousness *Awareness of external stimuli and one's own mental activity,* 14, 331–332
  absence of awareness and, 334–336
  analyzing, 332–333
  dreaming and, 349–351
  early research on, 14–15, 16–17
  functions of, 333
  hypnosis and, 351–353
  levels of, 333–334
  meditation and, 354–355
  neuropsychology of, 338
  psychoactive drugs and, 355–367
  sleep and, 339–349
  states of, 338–339
Consciousness disturbances *Neuropsychological disorders in which there are impairments in the ability to be aware of the world,* 816–819
Consciousness state *The characteristics of consciousness at any particular moment,* 338–339
Consensus
  in attribution, 704–705
  groupthink and, 764
Consequences Test, 403
Conservation *The ability to recognize that the important properties of a substance remain constant despite changes in shape, length, or position,* 476
Consideration, leadership and, 797–798
Consistency, in attribution, 705–706
Construct validity, 380
Constructive memory, 259–260
Constructivist approach *An approach to perception taken by those who argue that the perceptual system uses fragments of sensory information to construct an image of reality,* 158–159
Consumer psychologists, 10
Contact hypothesis *The idea that stereotypes and prejudice toward a group will diminish as contact with the group increases,* 717
Contact lenses, 122
Content validity, 380
Context
  expectancy and, 180
  sociocultural, 598
Context-dependent memories, 257
Context-specific memory (context-specific learning) *Memory that can be helped or hindered by similarities or differences between the context in which it is learned and the context in which it is recalled,* 257
Contingencies, in behavior therapy, 663
Continuity, in perceptual grouping, 168
Continuous positive airway pressure (CPAP), 347
Continuous reinforcement *A pattern in which a reinforcer is delivered every time a particular response occurs,* 214
Contralateral representations, 112
Control
  expectation of, 224
  helplessness and, 223–224
  perceived, 551, 708–709
  stress mediators and, 535–536
Control group *In an experiment, the group that receives no treatment or provides some other baseline against which to compare the performance or response of the experimental group,* 43
Control questions, in lie detection, 451–452
Convenience samples, 47
Conventional reasoning *Moral reasoning that reflects the belief that morality consists of following rules and conventions,* 506
Convergent thinking *The ability to apply logic and knowledge to narrow down the number of possible solutions to a problem or perform some other complex cognitive task,* 404
Conversion disorder *A somatoform disorder in which a person displays blindness, deafness, or other symptoms of sensory or motor failure without a physical cause,* 616
Cooperation *Any type of behavior in which people work together to attain a goal,* 758
  promoting, 760–761
  social dilemmas and, 758–760
Coping, with stress, 526, 536–540, 550–552
Copycat violence, 729
Cornea *The curved, transparent, protective layer through which light rays enter the eye,* 121–122
Coronary heart disease (CHD), 545–546. *See also* Heart disease
Corpus callosum *A massive bundle of fibers that connects the right and left cerebral hemispheres and allows them to communicate with each other,* 91
Correct rejection, signal detection theory, 163
Correlation coefficient *A statistic,* r, *that summarizes the strength and direction of a relationship between two variables,* 53–55, 379, A16–A17
Correlation *In research, the degree to which one variable is related to another,* 53–55
Correlation *vs.* causation, 42
Correlational study *A research method that examines relationships between variables in order to analyze trends in data, test predictions, evaluate theories, and suggest new hypotheses,* 41–42, 60
Corticosteroids, 529
Cortisol, 104
Counseling psychology, 6–7, 652, 659
Counterproductive work behavior (CWB), 791
Countertransference, 655
Couples therapy *A form of therapy focusing on improving communication between partners,* 670
The Courage to Heal (Bass & Davis), 269
Covert attention, 185–186
Covert orienting, 185
CPAP. *See* Continuous positive airway pressure
CR. *See* Conditioned response
Crack (cocaine), 361
Creative intelligence, 396
Creativity *The ability to produce new, high-quality ideas or products,* 403
  cognitive abilities and, 403–404
Criterion validity, 380
Critical incidents, 776

Critical period *An interval during which certain kinds of growth must occur if development is to proceed normally,* 321, 469
Critical thinking *The process of assessing claims and making judgments on the basis of well-supported evidence,* 31, 33–34
  myths and, 32
  scientific research and, 34–35, 59
  statistics, research methods, 55–57
Cross-cultural psychology, 27
Cross-sectional studies, 400–401
Cross-sequential with resampling design, 400
Crowding, 750
Crystallized intelligence *The specific knowledge gained as a result of applying fluid intelligence,* 394, 401, 510
CS. *See* Conditioned stimulus
Cultural familial intellectual disability *Cases of mild cognitive disability for which there is no obvious genetic or environmental cause,* 406
Culture of honor, 745–746
Culture *The accumulation of values, rules of behavior, forms of expression, religious beliefs, occupational choices, and the like for a group of people who share a common language and environment,* 25–27
  abnormality and, 597, 598
  achievement motivation and, 437–438
  advertising, values in, 26
  aggression and, 745–746
  alcohol and, 357, 601, 642
  altered states of consciousness and, 339
  attachment and, 488
  attitude change and, 712
  attributions and, 705–706
  clothing and, 730
  cognitive development and, 481–482
  collectivist, 25–26, 492, 506, 582–583, 678, 679, 699, 706, 712, 732, 761
  communication styles and, 26–27
  depression and, 601
  emotional expression and, 457–458
  food selection and, 424
  impact of, 26
  individualist, 25–26, 213, 312, 437, 582–583, 706–707, 712, 745
  language and, 325–326
  learning and, 232–235, 237
  love and marriage and, 722–723
  parenting styles and, 492–493
  perception and, 159, 181–182
  personality and, 581–583
  psychological disorders and, 601–602
  psychotherapy and, 678–679
  self-esteem and, 581–583
  sexual behavior and, 432
  sleep patterns and, 342
  social loafing and, 731–731
  social norms and, 597, 729–730
  somatoform disorders and, 618
  suicide and, 621–622
  teaching styles and, 232
Culture-fair tests, 392, 393
Culture-general disorder, 601
Curandero, 339
Cutaneous senses *Senses of touch, temperature, pain, and kinesthesia,* 141
  pain, 143–149, 151, 155
  proprioception, 149–151, 155
  stimulus, touch receptors and, 141–142
  temperature, 143
  touch information, encoding, 142–143
  touch receptors, adaptation, 142
  touch, temperature and, 141
CWB. *See* Counterproductive work behavior
Cyberchondria, 609
Cyclothymic personality (cyclothymic disorder) *An affective disorder characterized by an alternating pattern of mood swings that is less extreme than that of bipolar disorders,* 623
Cymbalta, 684

Daily hassles, 526–527
Dark adaptation *The increasing ability to see in the dark as time in the dark increases,* 123
Data *Numbers that represent research findings and provide the basis for research conclusions,* 35
Data set, 35
Day care, 41–42, 488–490
DBS. *See* Deep brain stimulation
Deafness, 115–117
Death and dying, 516–517, 524
Death instincts, 559
Decay theory *A description of forgetting as the gradual disappearance of information from memory,* 265
Decibels, 113–114
Decision making, 309. *See also* Problem solving
  attribute comparison, 310
  biases, flaws in, 310–312
  evaluating options, 310
  group processes, 312–314
  probability estimation, 310
  reaction time in, 288–289
  stress and, 531–532
Decisions under uncertainty, 309
Decomposition, 301
Decomposition strategy, 301
Deductive reasoning, 296
Deep Blue, 308
Deep brain stimulation (DBS), 682
Deep structure *An abstract representation of the underlying meanings of a given sentence,* 316
Defense mechanism *A psychological response that helps protect a person from anxiety and guilt,* 559–560
  personality, psychodynamic approach, 559–560
Defensive aggression, 744
Deficiency orientation, 441
Degrees of freedom (df) *The total sample size or number of scores in a data set, less the number of experimental groups,* A19
Deindividuation *A psychological state occurring in group members that results in loss of individuality and a tendency to do things not normally done when alone,* 730, 731
Deinstitutionalization, 690–691
Delirium *Periods of abnormally impaired or abnormally elevated levels of consciousness,* 816–817
Delusions *False beliefs, such as those experienced by people suffering from schizophrenia or extreme depression,* 620
Delusions of influence, 628
Delusions of persecution, 628
Dementia *Neuropsychological disorders in which there are significant and disruptive impairments in memory, as well as perceptual ability, language, or learned motor skills,* 84, 826–829
Dendrites *Neuron fibers that receive signals from the axons of other neurons and carry those signals to the cell body,* 66, 68
Denial, 818
Depakote, 685
Dependent variable *In an experiment, the factor affected by the independent variable,* 43
Depolarization, cell membrane, 67
Depression, 620–621
  in adolescence, 508
  anxiety and, 606
  attributional style and, 626
  cultural factors in, 601
  diathesis-stress model and, 602
  gender differences in, 36–37, 601
  helplessness and, 224
  herbal remedy for, 684, 687
  psychoactive drugs for, 684
  psychological disorders and, 601
  social-cognitive theories, 626
  stress and, 534, 539
  suicide and, 621–623
Depressive disorders, 620–621
  bipolar disorder, 623–625
  suicide and depression, 621–623
Depth cues, 170–173, 175, 181–182
Depth perception *The ability to perceive distance,* 170–173, 176
Desaturation, color, 129
Descriptive norms, 730

Descriptive statistics *Numbers that summarize a set of research data,* 51–55, A13, A14
Desensitization hierarchy, 661
Developed ability, intelligence as, 384
Developmental psychologists *Psychologists who seek to understand, describe, and explore how behavior and mental processes change over a lifetime,* 6
Developmental psychology *The psychological specialty that documents the course of social, emotional, moral, and intellectual development over the life span,* 6, 465
Developmentally disabled, 405–406
Deviance, 597
Df. *See* Degrees of freedom
Diagnostic and Statistical Manual of Mental Disorders (DSM), 433, 598, 604, 606–607
Diagnostic labels, 606–607
Diathesis, 602
Diathesis-stress approach, 617–618, 632–633
Diathesis-stress model *The notion that psychological disorders arise when a predisposition for a disorder combines with sufficient amounts of stress to trigger symptoms,* 534, 602
Diazepam, 685
DID. *See* Dissociative identity disorder
Difference threshold, 165
Diffusion of responsibility, 753
Diffusion tensor imaging (DTI), 76
Dimebolin, 828
Dimebon, 828
Directed lie test, 452
Disconnection syndrome, 808
Discrimination, 718–720, 779
Discriminative conditioned stimuli *Stimuli that signal whether reinforcement is available if a certain response is made,* 211–212
Diseases of adaptation *Illnesses that are caused or worsened by stressors,* 530
Dishabituation, 182–183, 199
Disorganized attachment, 488
Disorganized schizophrenia, 630
Dispositional optimism, 540
Dissociation theory, 352
Dissociative amnesia *A dissociative disorder marked by a sudden loss of memory,* 618
Dissociative disorders *Rare conditions that involve sudden and usually temporary disruptions in a person's memory, consciousness, or identity,* 618–620
Dissociative identity disorder (DID) *A dissociative disorder in which a person reports having more than one identity,* 618–619
Dissonance, 711
Distance, perception of, 169–173, 193
Distinctiveness, in attribution, 705
Distracting style, 626
Distress, 597–598
Distributed practice *The spacing of study sessions over days or weeks,* 277
Distributed training, 782
Divalproex, 685
Divergent thinking *The ability to think along many alternative paths to generate many different solutions to a problem,* 403–404
Divided attention, 187–189
Divorce, 500, 514, 724, A11
DNA (deoxyribonucleic acid) *The material that makes up chromosomes and provides the genetic code,* A5
Dodo Bird Verdict, 673
Dolphins, learning language and, 324
Dominate genes, A6
Dopamine *A neurotransmitter used in the parts of the brain involved in regulating movement and experiencing pleasure,* 100–101
  alcohol and, 358
  amphetamines and, 360
  marijuana and, 364, 366, 367
  meditation and, 355
  schizophrenia and, 632, 690
  stimulants and, 360–362
Dopamine neurons, 274
Dopaminergic systems, 100
Double-blind design *A research design in which neither the experimenter nor the participants know who is in the experimental group and who is in the control group,* 45
Down Syndrome, 405–406
Downers, 359
Downward social comparison, 698
Dramatic-erratic cluster, 634
Dreaming *The experience of storylike sequences of images, sensations, and perceptions occurring mainly during REM sleep,* 349–351
Drive *A psychological state of arousal created by an imbalance in homeostasis that prompts an organism to take action to restore the balance and reduce the drive,* 417
Drive reduction theory *A theory of motivation stating that motivation arises from imbalances in homeostasis,* 417–418
Drug abuse *The self-administration of psychoactive drugs in ways that deviate from cultural norms and cause serious problems for the user,* 356–357
Drug therapy. *See* Psychoactive drug
Drug tolerance *A condition in which increasingly larger drug doses are needed to produce a given effect,* 356, 641
Drug withdrawal *Symptoms associated with discontinuing the use of a habit-forming substance,* 356
Drugs
  abuse of, 356–357
  CNS depressants, 358–360
  CNS stimulants, 360–363
  expectations, effects and, 357–358
  hallucinogenics, 363–367
  prenatal risks and, 469
  psychopharmacolgy, 355–356

  - selection process, 777–779
- Employee training programs, 780, 780–781
  - designing, 781–782
  - evaluation, 782–783
- **Encoding specificity principle** *A principle stating that the ability of a cue to aid retrieval depends on the degree to which it taps into information that was encoded at the time of the original learning,* 256
- **Encoding (memory)** *The process of acquiring information and entering it into memory,* 242
  - in long-term memory, 253–254
  - in short-term memory, 250–251
- **Encoding (sensory systems)** *Translating the physical properties of a stimulus into a pattern of nerve cell activity that specifically identifies those properties,* 111–112, 153
- Encodings, 575
- Encounter groups, 580
- Endocannabinoids, 146, 364, 422
- **Endocrine system** *Cells that form organs called glands and that communicate with one another by secreting chemicals called hormones,* 102–105, 106–107
- **Endorphins** *A class of neurotransmitters that bind to opiate receptors and moderate pain,* 101–102, 146–147
- **Engineering psychology** *A field in which psychologists study human factors in the use of equipment and help designers create better versions of that equipment,* 5–6, 793
- Enteristatin, 422
- Environment, 47–51
  - aggression and, 750
  - alcoholism and, 642
  - behavioral genetics and, A10–A12
  - cognitive development and, 482–484
  - creativity and, 404
  - helping behavior and, 754
  - interpersonal attraction and, 720
  - IQ and, 384–386, 388–389, 391
  - personality and, 570–572
  - schizophrenia and, A10
  - sexual orientation and, 435
  - youth violence and, 504
- **Environmental psychologists** *Psychologists who study the effects of the physical environment on behavior and mental processes,* 9–10
- **Environmental psychology** *The study of the relationship between behavior and the physical environment,* 9–10, 750
- **Epigenetics** *The study of potentially inheritable changes in gene expression that are caused by environmental factors that do not alter a cell's DNA,* 51, 572, 613
- Epilepsy, 75, 101, 151–152
- Epinephrine, 100
- **Episodic memory** *Memory of an event that happened while one was present,* 243, 260–261, 510
- Epival, 685
- Equal opportunity, 779–780
- Equanil, 685
- Equipotentiality, 205
- ERG theory. *See* Existence, relatedness, growth theory
- Eros, 559
- Erotic sensations, 151–152
- **Escape conditioning** *A type of learning in which an organism learns to make a particular response in order to terminate an aversive stimulus,* 209–211, 221
- Escitalopram, 684
- EST. *See* Electroconvulsive shock therapy
- Estradiol, 430

Estrogens *Sex hormones that circulate in the bloodstream of both men and women; more estrogens circulate in women than in men,* 103, 430–431
ESTs. *See* Empirically supported therapies
Ethical guidelines, 57–58, 60
Ethical Principles of Psychologists and Code of Conduct (APA), 58, 680
Ethnic group differences
  in alcohol use, 642
  in IQ scores, 387–388
  in job satisfaction, 788
  in psychoactive drug responses, 686–687
  in suicide rates, 622
Ethnic identity *The part of a person's identity associated with the racial, religious, or cultural group to which the person belongs,* 505
Evidence based practice *The selection of treatment methods based mainly on empirical evidence of their effectiveness,* 674
Evoked potential *A small, temporary change in EEG voltage in the brain that is caused by some stimulus,* 289
Evolution, 20
Evolutionary approach *An approach to psychology that emphasizes the inherited, adaptive aspects of behavior and mental processes,* 20
  helping behavior and, 755–756
  to psychology, 20
Excitation transfer theory *The theory that physiological arousal stemming from one situation is carried over to and enhances emotional experience in an independent situation,* 454, 749
Excitatory postsynaptic potential *A postsynaptic potential that depolarizes the neuronal membrane, making the cell more likely to fire an action potential,* 68–69
Exelon, 828
Exhaustion stage, stress response, 529
Existence needs, 442, 784
Existence, relatedness, growth (ERG) theory *A theory of motivation that focuses on employees' needs at the level of existence, relatedness, and growth,* 442, 784
Existential therapy, 659
Expectancies
  alcohol consumption and, 357
  in classroom, 390
  cognitive person variables, 575
  perception and, 186
  reaction time, 288
  Rotter's expectancy theory, 574
Expectancy theory *A theory of workplace motivation in which employees act in accordance with expected results and how much they value those results,* 574–575, 784–785
Expectations
  drug effects and, 357–358
  helplessness, 224
  perception and, 224
  placebo effect and, 44–45
Expected value *The total benefit to be expected if a decision were to be repeated several times,* 310
Experiment *A situation in which the researcher manipulates one variable and then observes the effect of that manipulation on another variable, while holding all other variables constant,* 42–43, 60
  experimenter bias, 45
  placebo effects, 44–45
  random variables, 43–44
Experimental group *In an experiment, the group that receives the experimental treatment,* 42–43
Experimental neuropsychologists, 806
Experimental psychologists, 5
Experimenter bias *A confound that occurs when an experimenter unintentionally encourages participants to respond in a way that supports the experimenter's hypothesis,* 45
Experimenter expectancies, 45
Expert power, 739
Expert systems, 308
The Experts Speak (Cerf & Navasky), 307
Explicit memory *The process of intentionally trying to remember something,* 243–245
Exposure therapy *Behavior therapy methods in which clients remain in the presence of strong anxiety-provoking stimuli until the intensity of their emotional reactions decrease,* 664
Expressed emotion. *See* Emotional expression
Expressive aprosodia, 824–825
External attribution, 704
Externalizing disorders, 638–639
Extinction *The gradual disappearance of operant behavior due to elimination of rewards for that behavior,* 202
  in behavior therapy, 663–664
  in classical conditioning, 202–203, 207
  in operant conditioning, 215–216
Extrapyramidal motor system, 447
Extraversion, 562, 566, 567
The Extreme Zone (television), 742
Extrinsic motivation, 436
Eye, 121–125
Eye convergence *A depth cue involving the rotation of the eyes to project the image of an object on each retina,* 172
Eye movement desensitization and reprocessing (EMDR), 31–32
  case studies, 38
  critical thinking and, 33–35
  experiments, 42–43
  inferential statistics, 55
  observational methods, 37
  placebo effect, 44–45
  theories, 36
Eyewitness Evidence: A Guide for Law Enforcement (U.S. Department of Justice), 263–264
Eyewitness testimony, 12, 261–264
Eysenck's biological trait theory, 568–569

Facet approach, job satisfaction, 785–786
Facial expressions, 451, 456–459
Facial feedback hypothesis, 451
Facilitated communication (FC), 55–57
Factor analysis, 394
False alarm, 163
False Memory Syndrome Foundation, 270
Family studies
  behavior genetics, 49–50
  bipolar disorders and, 624
  schizophrenia, 49
Family system, 669
Family therapy *Treatment of two or more individuals from the same family,* 669–670
Family ties, 755
Family-friendly work policies, 788
FC. *See* Facilitated communication
Feature detectors *Cells in the cortex that respond to a specific feature of an object,* 128, 178
Fechner's law, 166
Feedback
  in employee training programs, 801
  systems for, 73
Feeding Infants and Toddlers Study, 427
Feeling-of-knowing experience, 259
Fetal alcohol syndrome *A pattern of physical and mental defects found in babies born to women who abused alcohol during pregnancy,* 469
Fetal stage, 468
Fetus *The developing individual from the third month after conception until birth,* 468
FI reinforcement. *See* Fixed-interval reinforcement
Fight-or-flight syndrome (fight-flight reaction) *A physical reaction triggered by the sympathetic nervous system that prepares the body to fight or to run from a threatening situation,* 72, 104, 448, 528
Figure ground discrimination *The ability to organize a visual scene so that it contains meaningful figures set against a less relevant ground,* 167
Figure, in perceptual organization, 167, 176
Fissures, 87
Five-factor personality model (Big Five model) *A view based on factor-analytic studies suggesting the existence of five*

basic components of human personality: openness, conscientiousness, extraversion, agreeableness, and neuroticism, 567–568
Fixed-action patterns, 415
Fixed-interval (FI) reinforcement *A partial reinforcement schedule that provides reinforcement for the first response that occurs after some fixed time has passed since the last reward,* 214
Fixed-ratio (FR) reinforcement *A partial reinforcement schedule that provides reinforcement following a fixed number of responses,* 214
Flashbacks, 533
Flashbulb memories, 254
Flavor, 140–141, 423–424
Flextime, 788, 794
Flight or freeze system (FSS), 569–570
Flooding *An exposure technique for reducing anxiety that involves keeping a person in a feared but harmless situation,* 664
Fluid reasoning, 377, 685
Fluoxetine, 684, 685
Fluvoxamine, 685
FMRI. *See* Functional magnetic resonance imaging; Functional MRI
Food, 423–424. *See also* Eating; Hunger
Food culture, 424
Foot-in-the-door technique, 736–737
Forebrain *The most highly developed part of the brain; it is responsible for the most complex aspects of behavior and mental life,* 82–84
Foreign accent syndrome, 90
Forensic psychologists *Psychologists who assist in jury selection, evaluate defendants' mental competence to stand trial, and deal with other issues involving psychology and the law,* 9
Forensic psychology, 9
Forgetting, 264–271
Formal concepts, 291
Formal operational stage *According to Piaget, the fourth stage in cognitive development, usually beginning around age 11, when abstract thinking first appears,* 476, 501
Formal reasoning *The process of following a set of rigorous procedures for reaching valid conclusions,* 295–297
Forward conditioning, 204
Fovea *A region in the center of the retina where cones are highly concentrated,* 123–124
FR reinforcement. *See* Fixed-ratio reinforcement
Fragile X syndrome, 406
Free nerve endings, 141
Frequency *The number of complete waveforms, or cycles, that pass a given point in space every second,* 113
Frequency-matching theory, 120
Freudian slips, 654
Frontotemporal degeneration (FTD), 823, 828
Frustration-aggression hypothesis *A proposition that frustration always leads to some form of aggressive behavior,* 748–749
FSS. *See* Flight or freeze system
FTD. *See* Frontotemporal degeneration
Fugue reaction (dissociative fugue) *A dissociative disorder involving sudden loss of memory and possible assumption of a new identity in a new location,* 618
Functional analysis *Analyzing behavior by studying what responses occur under what conditions of operant reward and punishment,* 573–574
Functional fixedness *A tendency to think about familiar objects in familiar ways that may prevent using them in other ways,* 305, 531
Functional magnetic resonance imaging (fMRI), 75–80, 289–290
Functional MRI (fMRI), 74, 75, 93, 273
Functionalism, 16–17
Fundamental attribution error *A bias toward overattributing the behavior of others to internal causes,* 706
Fundamental frequency, 115

g *A general intelligence factor that Charles Spearman postulated as accounting for positive correlations between people's scores on all sorts of cognitive ability tests,* 394
GABA. *See* Gamma-amino butyric acid
GAD. *See* Generalized anxiety disorder
Galanin, 422
Galantamine, 828
Galvanic skin resistance (GSR), 161, 699
Gambler's fallacy, 312
Gambling, 79
Gamma hydroxybutyrate (GHB), 360
Gamma-amino butyric acid (GABA) *A neurotransmitter that inhibits the firing of neurons,* 101, 358
Ganglion cells *Cells in the retina that generate action potentials,* 124–125
  color coding and, 133
  pathways, to brain, 127
GAS. *See* General adaptation syndrome
Gases, 102
GATB. *See* General Aptitude Test Battery
Gate control theory of pain *A theory suggesting that a functional "gate" in the spinal cord can either let pain impulses travel upward to the brain or block their progress,* 145–146
GDNF. *See* Glial cell line-derived neurotrophic factor
Gender
  Alzheimer's disease and, 511
  conformity and, 735–736
  depression and, 626
  emotional expression and, 459
  job satisfaction and, 788

  sexuality and, 432
  socialization of, 497–498
  stereotype threat effect, 384
Gender schemas *The generalizations children develop about what toys, activities, and occupations are "appropriate" for males and for females,* 498–499
Gene therapy, 116–117
General adaptation syndrome (GAS) *A three-stage pattern of responses triggered by the effort to adapt to any stressor,* 528–530
General Aptitude Test Battery (GATB), 378
Generalized anxiety disorder (GAD) *A condition that involves relatively mild but long-lasting anxiety that is not focused on any particular object or situation,* 611
Generalized arousal, 749–750
Generalized social phobia, 611
Generativity *Adult concerns about producing something that may be of benefit to others in the future,* 515
Genes *The biological instructions, inherited from both parents and located on the chromosomes, that provide the blueprint for physical development,* A5
  behavior and, A9–A10
  dominant, A6
  multiple traits and, A9
  recessive, A6
Genetics *The biology of inheritance. chromosomes Long, thin structures in every biological cell that contain genetic information,* A5–A6
  aggression and, 743–745
  alcohol dependence and, 359
  antisocial personality disorder and, 635–636
  anxiety disorders and, 613
  arousal and, 569, 636
  biology of, A5–A6
  history of research, A6–A7

Genetics (*continued*)
  history of research and, A6–A7

  personality traits and, 570–572
  schizophrenia and, 631–632, A10
Genital stage *The last of Freud's psychosexual stages of personality development, which begins during adolescence, when sexual impulses appear at the conscious level,* 561
Genomic imprinting, 49
Genotype *The full set of genes, inherited from both parents, contained in twenty-three pairs of chromosomes,* A6
Genuineness, 658
Geodon, 683
Germinal stage, 468
Gestalt, 168
Gestalt laws (principles), 168–169
Gestalt psychologists, 15, 168
Gestalt psychology, 659
Gestalt therapy *An active treatment designed to help clients get in touch with genuine feelings and disown foreign ones,* 15, 659
GHB. *See* Gamma hydroxybutyrate
Gifted *A term referring to people who show remarkably high levels of accomplishment or promise for such accomplishment in particular cognitive domains,* 404–405
Glands *Organs that secrete hormones into the bloodstream,* 104
Glial cell line-derived neurotrophic factor (GDNF), 96
Glial cells *Cells in the nervous system that hold neurons together and help them communicate with one another,* 65
Global approach, job satisfaction, 785
Glove anesthesia, 617
Glucose, 421
Glutamate *An excitatory neurotransmitter that helps strengthen synaptic connections between neurons,* 101
Goal setting, 438
Goal-setting theory *A theory of workplace motivation focused on the idea that employees' behavior is shaped by their intention to achieve specific goals,* 785
GPA. *See* Grade-point average
Grade-point average (GPA), 373
Gradient of texture *A graduated change in the texture, or grain, of the visual field, whereby objects with finer, less detailed textures are perceived as more distant,* 171–172
Gradients, 171
Gradual exposure, 689
Graduate Record Examination (GRE), 378
Grammar *A set of rules for combining the words used in a given language,* 315
Grandeur, delusions of, 628, 630
Graphic rating forms, 776
Grasping reflex, 472
Gray's reinforcement sensitivity theory, 569–570
GRE. *See* Graduate Record Examination
Ground, in perceptual organization, 167
Group differences
  in behavioral genetics, A8
  in IQ scores, 386–388
Group factors, in cognitive ability, 394
Group identity, 701

  nonstate theories of, 352
  pain and, 144
  role theory of, 352
  state theories of, 352
  surgery and, 353
Hypnotic susceptibility *The degree to which a person responds to hypnotic suggestions,* 351
Hypochondriasis *A somatoform disorder involving strong, unjustified fear of having physical illness,* 616–617
Hypomania, 623
Hypothalamic-pituitary-adrenocortical (HPA) system, 528–529
Hypothalamus *A structure in the forebrain that regulates hunger, thirst, and sex drive,* 82–83, 98, 99, 103–104
  circadian rhythm and, 344
  hunger and, 422
  reinforcement and, 217
  sensory systems and, 138
  sexual behavior and, 431
Hypothesis *In scientific research, a specific, testable proposition about a phenomenon,* 34
Hysteria, 616

ICD-10. *See International Classification of Diseases*
ICIDH-2. *See International Classification of Impairments, Disabilities and Handicaps*
Iconic memory *The sensory register for visual information,* 249
Id *The unconscious portion of personality that contains basic impulses and urges,* 559
Ideational apraxia, 825
Identity, 505–506, 700–701
Identity crisis *A phase during which an adolescent attempts to develop an integrated self-image,* 508
Ideomotor apraxia, 825
Illness
  immune system and, 544
  stress and, 543–547
  stress, cardiovascular system and, 545–547
Illusory correlation, 716
Image *A mental representation of visual information,* 294–296
Immediate memory span *The maximum number of items a person can recall perfectly after one presentation of the items,* 251
Immune system *The body's first line of defense against invading substances and microorganisms,* 544
  illness and, 544
  stress and, 544–545
Impaired functioning, 598
Implicit memory *The unintentional influence of prior experiences,* 243–245, 480
Implicit social cognitions, 245
Implicit theories, 704
Impressions, 702–704
In vitro fertilization, 513
Inattentional blindness, 187
In-basket excercise, at assessment centers, 773
Incentive theory *A theory of motivation stating that behavior is directed toward attaining desirable stimuli and avoiding unwanted stimuli,* 418–420
Inclusive fitness, 755
Incomplete knowledge, 259
Incus, in ear structure, 115
Independent variable *The variable manipulated by the researcher in an experiment,* 43–44, 85, A13
Individual analysis, 655
Individual temperament, 484–486
Individualist cultures, 25–26, 583, 712
  achievement motivation and, 437
  aggression and, 745
  attributes and, 312
  dissonance and, 712
  fundamental attribution error and, 706–707

Individualist cultures (*continued*)
  personality and, 582–583
  reinforcement, 213
Inductive reasoning. *See* Informal reasoning
Industrial and organizational psychologists *Psychologists who study ways to improve efficiency, productivity, and satisfaction among workers and the organizations that employ them,* 9, 769–770
  case studies, 39
Industrial and organizational (I/O) psychology *The science of behavior and mental processes in the workplace,* 9, 769–770
  employee characteristics, measuring, 772–774
  employee motivation, 783–785
  employee recruitment and selection, 777–780
  employee training, 780–783
  job analysis, 771–772
  job performance, measuring, 774–775
  job satisfaction, 785–791
  knowledge, skills, abilities, and other characteristics, 770–771
  occupational health psychology, 792–795
  performance appraisal, methods of, 775–777
  teaching, 770
  work groups, work teams and, 795–798
Infancy
  attachment in, 486–488
  brain development in, 472
  cognitive development, 477–478, 481–482
  concrete operations and, 476
  developmental stages, 478
  formal operational stage and, 476
  knowledge, development of, 472–474
  language development in, 318–320
  memory, 478
  perception and, 182–184
  preoperational development, 475–476
  reflexes and motor skills in, 471–472
  sensorimotor development, 474–475
  temperament in, 484–486
  vision and other senses, 470–471
Infant vocalizations (babblings) *The first sounds infants make that resemble speech,* 318–319
Infantile amnesia, 480
Inferences, 17, 295
Inferential statistics *A set of mathematical procedures that help psychologists make inferences about what their research data mean,* 51, 60, A13, A17
Inflections, 321
Informal reasoning *The process of evaluating a conclusion, theory, or course of action on the basis of the believability of evidence,* 297–298
Information processing *The process of taking in, remembering or forgetting, and using information,* 18
  aging and, 510
  in childhood, 478–480
  measurement of, 288–290
  as nervous system function, 64, 68, 73
  schizophrenia and, 631
Information-processing model *An approach to the study of intelligence that focuses on mental operations, such as attention and memory, that underlie intelligent behavior,* 395
Information-processing model of memory *A memory model in which information is seen as passing through sensory memory, short-term memory, and long-term memory,* 247–248
Information-processing system *Mechanisms for receiving information, representing it with symbols, and manipulating it,* 287–288
Ingroup *Those whom we perceive as being similar to ourselves,* 706, 798
Inhibitory postsynaptic potential *A postsynaptic potential that hyperpolarizes the neuronal membrane, making a cell less likely to fire an action potential,* 69
Initiating structure, 798
Injunctive norms, 730
Inpatients, 652
Insanity Defense Reform Act, 644
Insecure attachment, 487–488, 563
Insight *A sudden understanding about what is required to solve a problem,* 226–227
Insomnia *A sleep disorder involving difficulty falling asleep or staying asleep at night,* 346–347
Instinct, 558
Instinct doctrine *A view that explains human behavior as motivated by automatic, involuntary, and unlearned responses,* 415–416, 415–417
Instinctive behaviors *Innate, automatic dispositions toward responding in a particular way when confronted with a specific stimulus,* 415
Institutional review boards (IRBs), 57
Instrumental aggression, 792
Instrumental conditioning, 208
Insular cortex, 144
Insulin, 421
Integrative therapists, 653
Integrity tests, 772
Intellectual disability, 405–406
Intelligence *Personal attributes that center around skill at information processing, problem solving, and adapting to new or changing environments,* 374
  information-processing model, 395
  multiple, 398–399
  psychometric approach, 394–395
  triarchic theory of, 396–398
Intelligence quotient (IQ) *An index of intelligence that reflects the degree to which a person's score on an intelligence test deviates from the average score of others in the same age group,* 375, A15–A16
  in classroom, 390–391
  genetics and, A7–A9
  genetics research and, A7
  giftedness, 404–405
  group differences in, 386–388
  influences on, 384–386, 391
  intellectual disability, 405–406
  learning disabilities, 406–407
  population distribution of, 378
  quality of tests for, 379
  raising of, conditions, 388–390
  tests for, 376–378
  tests for, reliability and validity, 381–383
Intelligence tests, 374
  bias of, 391–393
  current, 376–378
  history of, 374–376
  statistical reliability, 381–383
  statistical validity, 381–383
Interdependence, in intimate relationships, 721
Interference *The process through which either the storage or the retrieval of information is impaired by the presence of other information,* 265–266
Internal attribution, 704
Internal noise, 162–163
Internal working models, 488
Internalizing disorders, 638–639
International Classification of Diseases (ICD-10), 603
International Classification of Diseases (WHO), 433
International Classification of Impairments, Disabilities and Handicaps (ICIDH-2), 603
Interneurons, 124
Interpersonal attraction, 720
  intimate relationships and, 721–722
  keys to, 720–721
  love and, 721–724
  marriage and, 723–724
Interpersonal conflict, 761–762
Interpersonal intelligence, 398–399
Interpersonal therapy, 656
Interposition *A depth cue whereby closer objects block one's view of things farther away,* 170
Interrater reliability, 606
Intervening variable, 413, 413–414
Interviews, 773
Intrapersonal intelligence, 398
Intrapsychic conflicts, 559
Intrinsic motivation, 436
Introspection, 14
Introversion, 562
Iodopsin, 123
IQ. *See* Intelligence quotient

IRBs. *See* Institutional review boards
Iris *The colorful part of the eye, which constricts or relaxes to adjust the amount of light entering the eye,* 121
Irresistible-impulse test, 644

Jaijin kyofusho, 611
James-Lange theory, of emotion, 449
Jet lag *A syndrome of fatigue, irritability, inattention, and sleeping problems caused by air travel across several time zones,* 343
Jigsaw technique, 717
JND. *See* Just-noticeable difference
Job analysis *The process of collecting information about jobs and job requirements that is used to guide hiring and training decisions,* 771–772
Job applicant interviews, 773
Job incumbents, 771
Job performance *A measure of how well employees are doing in various aspects of their work, usually recorded annually,* 774
  job satisfaction and, 790
  objective appraisal measures, 775
  performance criteria, 774–775
  subjective appraisal measures, 775–777
Job Satisfaction Survey, 786
Job satisfaction *The degree to which people like or dislike their jobs,* 785
  consequences of, 790–791
  factors affecting, 786–788
  genetics and, 788–790
  measuring, 785–786
Job-oriented approach, job analysis, 771
Just-noticeable difference (JND) *The smallest detectable difference in stimulus energy,* 165

Kendra's law, 681
Ketamine, 364
Kin selection, 756
Kinesthetic perception *The proprioceptive sense that tells you where the parts of your body are with respect to one another,* 150–151
Klonopin, 685
Knee-jerk reflex, 509
Knowledge
  development of, 472–476
  testing of, 377
Knowledge, skills, abilities, and other characteristics (KSAOs), 770–771
Kohlberg's stages of moral development, 506–507
Koro, 601–602
Korsakoff's psychosis (Korsakoff's syndrome) *An amnestic condition in people whose thiamine (vitamin B1) level is depleted by inadequate nutrition or alcoholism,* 275, 641, 815
KSAOs. *See* Knowledge, skills, abilities, and other characteristics
Kyol goeu, 601

Lamictal, 685
Lamotrigine, 685
Language disorders (aphasias) *Neuropsychological disorders in which there are disruptions in the ability to speak, read, write, and understand language,* 823–825
Language *Symbols and a set of rules for combining them that provides a vehicle for communication,* 314
  acquisition of, 320–322
  association cortex and, 90–91
  culture and, 325–326
  development of, 318–320
  elements of, 315–316
  nonhumans and, 322–325
  processing, 118
  speech and, 316–318
Largactil, 683
Laser-assisted in situ keratomileusis (LASIK), 122
Late adulthood, 509
  cognitive changes, 509–511
  death and dying in, 516–517
  longevity and, 517–518
  physical changes in, 509
  sleep patterns in, 341–342
  social changes, 515–516
Latency period *The fourth of Freud's psychosexual stages of personality development, in which sexual impulses lie dormant,* 561
Latent content, of dreams, 654
Latent learning *Learning that is not demonstrated at the time it occurs,* 225–226, 237
Lateral dominance (lateralization) *The tendency for one cerebral hemisphere to excel at a particular function or skill compared with the other hemisphere,* 91–94
Lateral geniculate nucleus (LGN), 126, 128
Lateral hypothalamus, 422
Lateral inhibition, 124
Lateralization. *See* Lateral dominance
Law, 12
Law, mental illness and, 643–645
Law of effect *A law stating that if a response made in the presence of a particular stimulus is followed by satisfaction, that response is more likely the next time the stimulus is encountered,* 208
Law of parsimony, 36
LCUs. *See* Life change units
Leader-membership exchange (LMX) theory *A theory suggesting that leaders tend to supervise ingroup and outgroup employees in different ways,* 798
Leadership, group, 762–764, 797–800
Learned association, 200
Learned behaviors, 659
Learned helplessness *Learning that responses do not affect consequences, resulting in failure to try to exert control over the environment,* 223, 237, 625–626
Learning disabilities *Conditions that may account for a significant discrepancy between a person's measured intelligence and academic performance,* 406–407
Learning goals, 436
Learning *The modification through experience of preexisting behavior and understanding,* 197–198
  active, 233–234
  aggression and, 745–746
  anxiety disorders and, 614–616
  application of research of, 232–235
  biopreparedness for, 205
  classical conditioning and, 200–207
  cognitive processes in, 222–229
  cultural factors, 232–235, 237
  insight and, 226–227
  instrumental conditioning and, 208
  latent, 225–226
  neural networks and, 221–222
  observational, 227–231, 614–615, 746
  operant conditioning and, 207–220
  prejudice and, 715
  skill, 234–235
  sleep deprivation and, 345
  social, 227
  stimuli and, 198–20
  teaching styles and, 232
Learning to learn, 227
Lecture notes, 278–279
Legitimate power, 739
Leniency error, 776
Lens *The part of the eye behind the pupil that bends light rays, focusing them on the retina,* 121
Leptin, 421–422
LES. *See* Life Experiences Survey
Lesion *An area of damaged tissue in the brain,* 807–808
Lesion analysis, 809
Leukocytes, 544
Levels-of-processing model of memory *The view that how well something is remembered depends on the degree to which incoming information is mentally processed,* 246
Lexapro, 684
LGN. *See* Lateral geniculate nucleus
Li Chi, 459
Libido *The psychic energy contained in the id,* 559
Librium, 685
Licensed professional counselors, 652

Lie detection, 451–452, 557
Life change units (LCUs), 526
Life changes and strains, 526
Life Experiences Survey (LES), 527
Life outcomes, 585
Life satisfaction, 515, 583
Life span, cognitive abilities and, 400–402
Light, 121
  conversion into images, 123–125
  depth perception and, 171–172
  focusing, 121–122
Light intensity *A physical dimension of light waves that refers to how much energy the light contains; it determines the brightness of light,* 121
Light rays, 121
Light wavelength *The distance between peaks in light waves,* 121
Light waves, 121
Likelihood principle, 169
Limbic system *A set of brain structures that play important roles in regulating emotion and memory,* 82, 446, 744, 815–816
Limits on memory, 297
Linear perspective *A depth cue whereby objects closer to the point at which two lines appear to converge are perceived as being at a greater distance,* 171
Linguistic determinism, 325
Linguistic intelligence, 398
Lip reading, 118
Lithium, 684–685
LMX theory. *See* Leader-membership exchange theory
Localization of function *The idea that specific psychological functions can be affected by damage to specific brain areas,* 807
Location, perception of, 169–173, 176
Locus coeruleus *A small nucleus in the reticular formation that is involved in directing attention,* 80, 346
Logic *A system of formulas for drawing valid conclusions,* 295–296
Logical reasoning, 295
Logical-mathematical intelligence, 398
Longevity, 517–518
Longitudinal studies, 400–401, 404, 583–585, 747
Long-term depression, 272
Long-term memory (LTM) *A relatively long-lasting stage of memory whose capacity to store new information is believed to be unlimited,* 253
  encoding, 253–254
  short-term memory and, 255–256
  storage capacity, 254
Long-term potentiation, 272
Looming *A motion cue involving a rapid expansion in the size of an image so that it fills the retina,* 173
Loose associations, 628
Loss aversion, 311
Loudness *A psychological dimension of sound determined by the amplitude of a sound wave,* 113
Love
  in adolescence, 502–504
  analyzing, 722–723
  intimate relationships and, 721–722
  marriage and, 723–724
  need for, 442
  triangular theory of, 723
Low-ball technique, 737
LSD (lysergic acid diethylamide), 363–364
LTM. *See* Long-term memory
Luchins jar problem, 305
Lucid dreaming *Awareness that a dream is a dream while it is happening,* 349
Luria-Nebraska Neuropsychology Battery, 810
Luvox, 685

Macrophage, 544
Magnetic resonance imaging (MRI), 5, 74–76, 353, 631, 814
Magnetic seizure therapy (MST), 682
Magnitude estimation, 165–167, 193
Maintenance rehearsal *Repeating information over and over to keep it active in short-term memory,* 246
Major depression (major depressive disorder) *An affective disorder in which a person feels sad and hopeless for weeks or months,* 620
Malingering, 616
Malleus, in ear structure, 115
Mania *An elated, very active emotional state,* 623
Manic depression, 623
Manifest content, of dreams, 654
Mantra, 354
MAOI. *See* Monoamine oxidase inhibitor
Marijuana, 257, 364–367
Marriage, 416, 512–514, 723–724
Marriage and family therapists, 652
Maslow's hierarchy, 441–443
Massed practice *A long period of concentrated study ("cramming"),* 277
Massed training, 782
Matching hypothesis *The notion that people are most likely to form relationships with those who are similar to themselves in physical attractiveness,* 721
Materialism, 332
Maturation *Natural growth or change that unfolds in a fixed sequence relatively independent of the environment,* 466
MCI. *See* Mild cognitive impairment
MDMA (3,4-methylenedioxymethamphetamine), 362–363
Mean *A measure of central tendency that is the arithmetic average of the scores in a set of data,* 52, A14
Means-end analysis, 301
Median *A measure of central tendency that is the halfway point in a set of data: Half the scores fall above the median, and half fall below it,* 52, A14
Medical model (neurobiological model) *A view in which psychological disorders are seen as reflecting disturbances in the anatomy and chemistry of the brain and in other biological processes,* 599–600
Meditation, 354–355
Medium, sound, 113
Medulla oblongata *An area in the hindbrain that controls blood pressure, heart rate, breathing, and other vital functions,* 80
Meiosis, A6
Melatonin, 344
Melodic intonation therapy, 90
Memory, 241. *See also* Amnesia

Network processing, 180–182
Neural network models, 72–73
  learning and, 222
  perception and, 180
  problem solving and, 309
Neural networks *Neurons that operate together to perform complex functions,* 70
  learning and, 221–222, 247
  problem solving and, 309
Neural plasticity *The ability to create new synapses and to change the strength of synapses,* 94, 106
  brain damage repair, 95–96
Neural receptors (receptors) *Sites on the surface of a cell that allow only one type of neurotransmitter to fit into them, triggering a chemical response that may lead to an action potential,* 110
Neural receptors *Specialized cells that detect certain forms of energy and transduce them into nerve cell activity,* 68
Neural stem cells *Special cells in the nervous system that are capable of dividing to form new tissue, including new neurons,* 95
Neurobiological model. *See* Medical model (neurobiological model)
Neurodegeneration, 813
Neurodegenerative diseases *Conditions in the brain that result in a gradual loss of nerve cells and of the cognitive or other functions in which those cells are normally involved,* 813
Neurodevelopmental abnormalities, 632
Neuroeconomics, 77
Neurofibrillary tangles, 827
Neurogenesis, 95
Neuroleptic drugs *Medications that alleviate the symptoms of severe disorders such as schizophrenia,* 683
NeuroImaging, 289–290
Neuromodulators, 422
Neurons *Fundamental units of the nervous system; nerve cells,* 65
  action potentials of, 66–68
  common features, 65–66
  communication between, 68–70, 105–106
  motor, 71–72
  sensory, 71–72
  special features, 66
Neuropeptide Y, 422
Neuropsychological assessment *Testing a patient's intelligence, memory, reading, motor coordination, and other cognitive and sensory functions in an effort to locate problems in the brain responsible for neuropsychological symptoms,* 810–811
Neuropsychological disorders, 813–829
Neuropsychologists, 805, 811
Neuropsychology *The subfield of psychology whose goal is to explore and understand the relationships among brain processes, human behavior, and psychological functioning,* 39, 805–807
  amnestic disorders, 813–816
  brain dysfunction mechanisms, 811–813

Nitric oxide, 102
Nogo protein, 96
Noise, 162–163
Nonassociative learning, 199

- **Nonconscious level** *A level of mental activity that is inaccessible to conscious awareness,* 334
- Nongenetic environmental factors, A11
- Nonlinear dynamics, 151
- **Nonprojective personality measures** *Paper-and-pencil tests containing direct, unambiguous items relating to the personality of the individual being assessed,* 586–588
- **Non-REM (NREM) sleep** *Sleep stages 1, 2, 3, and 4; they are accompanied by gradually slower and deeper breathing, a calm and regular heartbeat, reduced blood pressure, and slower brain waves. (Stages 3 and 4 are called* slow-wave sleep*.),* 340–342, 345–346
- Nonresponse error, 46
- Nonshared environmental factors, 571, A11
- **Nonstate theories of hypnosis** *Theories, such as role theory, proposing that hypnosis does not create an altered state of consciousness,* 352
- **Norepinephrine** *A neurotransmitter involved in arousal, as well as in learning and mood regulation,* 99–100, 448
- Norm violation criterion, 597
- Normal curve, A15
- **Normal distribution** *A dispersion of scores such that the mean, median, and mode all have the same value,* A15–A16
- **Norms** *Descriptions of the frequency at which particular scores occur, allowing scores to be compared statistically,* 379
  - in intelligence tests, 379
  - in neuropsychological tests, 806
- NREM sleep. *See* Non-REM sleep
- Nucleus, 65
- **Null hypothesis testing** *Evaluating whether the independent variable manipulated by the experimenter will have no effect on the dependent variable measured by the experimenter,* A13
- Nun study, 540

- **Obedience** *Changing behavior in response to a demand from an authority figure,* 737–739
  - factors affecting, 739–740
  - Milgram's studies of, 741–743
- **Obesity** *A condition in which a person is severely overweight, as measured by a body mass index greater than thirty,* 422, 425–427
- **Object permanence** *The knowledge that objects exist even when they are not in view,* 474
- Object relations theory, 562–563, 626
- Object relations therapy, 655
- Object superiority effect, 180–181
- Objective measures, of job performance, 775
- **Observational learning (social learning)** *Learning how to perform new behaviors by watching others,* 227–229, 237
- **Observational methods** *Procedures for systematically watching behavior in order to summarize it for scientific analysis,* 37, 59
- Observer ratings, 585
- **Obsessive-compulsive disorder (OCD)** *An anxiety disorder involving repetitive thoughts and urges to perform certain rituals,* 612–613
- OCB. *See* Organizational citizenship behavior
- Occlusion cue, in depth perception, 170
- **Occupational health psychology** *A field concerned with psychological factors that affect the health, safety, and well-being of employees,* 792
  - physical conditions and, 792–793
  - stress and, 795
  - work schedules, 794–795
- Occupational Information Network (O*NET), 772
- Occupations, fast-growing, 778
- OCD. *See* Obsessive-compulsive disorder
- **Ocular accommodation** *The ability of the lens to change its shape and bend light rays so that objects are in focus,* 122, 172
- Odd-eccentric cluster, 633
- Odor. *See* Olfaction
- **Oedipal complex** *A pattern described by Freud in which a boy has sexual desire for his mother and wants to eliminate his father's competition for her attention,* 561
- *Oedipus Rex* (Sophocles), 561
- Olanzapine, 683
- Olfaction, 136–138, 154
- **Olfactory bulb** *A brain structure that receives messages regarding smell,* 137
- **Olfactory perception** *The sense of smell,* 135
- O*NET. *See* Occupational Information Network
- **One-word stage** *A stage of language development during which children tend to use one word at a time,* 319–320
- **Operant** *A response that has some effect on the world,* 208–209
- Operant behavior
  - reinforcement, delay and size of, 213
  - reinforcement, schedules of, 214–215
  - schedules, extinction and, 215–216
  - secondary reinforcement, 213
  - shaping, 212–213
- **Operant conditioning** *A process through which an organism learns to respond to the environment in a way that produces positive consequences and avoids negative ones,* 207
  - applications of, 219–220
  - components of, 208–212, 236–237
  - effect of reinforcers and, 216–217, 237
  - operant behavior, 212–216, 237
  - punishment and, 217–218, 221, 237
  - puzzle box, 207–208
  - skinner box, 207–208
- Operant response, 208–209
- **Operational definition** *A statement that defines the exact operations or methods used in research,* 34
- **Opiates** *Psychoactive drugs, such as opium, morphine, and heroin, that produce sleep-inducing and pain-relieving effects,* 363
- Opium, 363
- Opponent colors, 132
- **Opponent-process theory** *A theory of color vision stating that color-sensitive visual elements are grouped into red-green, blue-yellow, and black-white elements,* 131–132, 199, 444
- **Optic chiasm** *Part of the bottom surface of the brain where half of each optic nerve's fibers cross over to the opposite side of the brain,* 126
- **Optic nerve** *A bundle of fibers composed of axons of ganglion cells that carries visual information to the brain,* 124
- Optimistic cognitive style, 224
- Optimistic explanatory style, 224
- **Oral stage** *The first of Freud's psychosexual stages of personality development, in which the mouth is the center of pleasure and conflict,* 560
- Orbitofrontal cortex, 140
- Organ of Corti, 115
- **Organizational citizenship behavior (OCB)** *A willingness to go beyond formal job requirements in order to help coworkers or the organization as a whole,* 790
- Organizational psychologists, 9, 214, 769
- Orgasm, 152, 431
- Otis-Lenon Mental Abilities Test, 378
- **Otoliths** *Small crystals in the fluid-filled vestibular sacs of the inner ear that, when shifted by gravity, stimulate nerve cells that inform the brain of the position of the head,* 150
- **Outgroup** *Those whom we perceive as being different from ourselves,* 706, 798

Person-oriented approach, job analysis, 771
Persuasion cues, 710
Pessimistic explanatory style, 224
PET. *See* Positron emission tomography scans
Phagocytosis, 544
Phallic stage *The third of Freud's psychosexual stages of personality development, in which the focus of pleasure and conflict shifts to the genital area,* 561
Phenomenological approach, 22
Phenomenologists, 656
Phenothiazines, 683
Phenotype *How an individual looks and acts, which depends on how inherited characteristics interact with the environment,* A6
Phenylketonuria (PKU), 406, A6
Pheromones *Chemicals released by one animal and detected by another that shape the second animal's behavior or physiology,* 137–138
Phi phenomenon, 15
Phobia *An anxiety disorder involving strong, irrational fear of an object or situation that does not objectively justify such a reaction,* 610
  classical conditioning and, 206
  learning and, 615–616
  as psychological disorder, 610–611
  treatment of, 661–662, 664
Phoneme *The smallest unit of sound that affects the meaning of speech,* 315
Phonemic paraphasias, 823
Photographic memory, 255
Photopigments *Chemicals in photoreceptors that respond to light and assist in converting light into nerve cell activity,* 123
Photoreceptors *Specialized cells in the retina that code light energy into nerve cell activity,* 123–124, 132–133, 135
Physical attractiveness, 721
Physical coping strategies, 551
Physical dependence, 356–357
Physiological arousal *A general level of activation that is reflected in several physiological systems,* 418
Physiological dependence, 641
Physiological needs, 418
Physiological psychologists, 5. *See also* Biological psychologists
Piaget's theory, 472–478
Pinna, 115
Pitch *How high or low a tone sounds,* 114–115, 118
PKU. *See* Phenylketonuria
Place theory *A theory that hair cells at a particular place on the basilar membrane respond most to a particular frequency of sound,* 119
Placebo *A physical or psychological treatment that contains no active ingredient but produces an effect because the person receiving it believes it will,* 44–45
Placenta, 468
Plaques, 84
Plasticity, in central nervous system, 94–96
Play therapy, 655
Pleasure principle *The id's operating principle, which guides people toward whatever feels good,* 559
Polarization, cell membrane, 67
Political correctness, 776
Polygenic traits *A term describing characteristics that are determined by more than one gene,* A6
Polygraphs, lie detection, 451–452
Ponzo illusion, 166
Pop psychologists, 36

  stress and, 550
Problem-focused coping, 536, 536–537, 540
Procedural knowledge (procedural memory) *A type of memory containing information about how to do things,* 243
Progestational hormones *Sex hormones that circulate in the bloodstream of both men and women, also known as progestins; more progestins circulate in women than in men,* 430–431
Progesterone, 430
Progestins, 430
Progressive muscle relaxation training *A procedure for learning to relax that involves tensing muscles and then releasing the tension in those muscles,* 551
Progressive relaxation training, 347, 661
Project Head Start, 389
Projective personality measures *Personality assessments made up of ambiguous stimuli that can be perceived and responded to in many different ways,* 586
Proposition *A mental representation of the relationship between concepts,* 292, 296
Propoxyphene, 363
Proprioceptive senses *The sensory systems that allow us to know about body position and what each part of our body is doing,* 141, 149
  kinesthetic perception, 150–151
  sense of equilibrium, 150–151
Proprioceptors *Receptors in muscles and joints that provide information to the brain about movement and body position,* 150
Prosopagnosia, 338
Protected classes, 779
Protégés, 791
Prototype *A member of a natural concept that possesses all or most of its characteristic features,* 291–292
Proximity
  obedience and, 740

  human diversity and, 24–28
  linkages within and beyond, 10–12, 27
  research in, 12–14, 27
  subfields, 5–10, 27
Psychometric approach *A way of studying intelligence that emphasizes analysis of the products of intelligence, especially scores on intelligence tests,* 394–395
Psychometrics *The scientific study and measurement of knowledge, abilities, attitudes, personality, and other psychological characteristics,* 394
Psychoneuroimmunology *A field of research on the interaction of psychological, social, behavioral, neural, hormonal, and immune system processes that affect the body's defenses against disease,* 544
Psychopathology *Patterns of thinking, feeling, and behaving that are maladaptive, disruptive, or uncomfortable for those who are affected or for those with whom they come in contact,* 595, 599, 601, 603
Psychopharmacology *The study of psychoactive drugs and their effects,* 355–356
Psychophysics *An area of research focusing on the relationship between the physical characteristics of environmental stimuli and the psychological experiences those stimuli produce,* 159
  absolute thresholds and, 160–161
  differences, judgement of, 164–165, 193
  magnitude estimation and, 165–167, 193
  signal detection theory in, 162–164
Psychosexual development *Periods of personality development in which, according to Freud, conflicts focus on particular issues,* 560
Psychosis, 604
Psychosocial rehabilitation, 691

Psychosurgery *Surgical procedures that destroy tissue in small regions of the brain in an effort to treat psychological disorders,* 682

Psychotherapy *The treatment of psychological disorders through talking and other psychological methods,* 651
  cultural factors in, 678–679
  drugs and, 688–689
  evaluation of, 671–681
  therapeutic relationship, 680–681
  therapy comparison, 673
  therapy selection, 674–677

Psychotomimetics, 363

PTSD. *See* Posttraumatic stress disorder

Puberty *The condition of being able, for the first time, to reproduce,* 500

Public goods dilemma, 760

Punishment *Presentation of an aversive stimulus or the removal of a pleasant stimulus; a therapy method that weakens undesirable behavior by following it with an unpleasant stimulus,* 217
  in behavior therapy, 664–665
  operant behavior and, 21–22, 217–219, 221, 237

Pupil *An opening in the eye, just behind the cornea, through which light passes,* 121

Puzzle box, 207–208

PVS. *See* Persistent vegetative state

Pyramidal motor system, 447

Quantitative psychologists *Psychologists who develop and use statistical tools to analyze research data,* 9

Quantitative psychology, 9

Quantitative reasoning, testing of, 377

Quetiapine, 683

Racism, aversive, 718. *See also* Prejudice

Random assignment. *See* Randomizing

Random sampling *The process of selecting a group of research participants from a population whose members all had an equal chance of being chosen,* 46

Random variable *In an experiment, a confound in which uncontrolled or uncontrollable factors affect the dependent variable, along with or instead of the independent variable,* 43–44

Randomizing *Assigning participants in an experiment to various groups through a random process to ensure that confounds are evenly distributed among the groups,* 44

Range *A measure of variability that is the difference between the highest and the lowest scores in a data set,* 53, A14

Rapid eye movement (REM) sleep *A stage of sleep in which brain activity and other functions resemble the waking state but that is accompanied by rapid eye movements and virtual muscle paralysis,* 340–342, 345–346, 346–347, 348, 349–350

RAS. *See* Reticular activating system

Rational-emotive behavior therapy (REBT) *A treatment designed to identify and change self-defeating thoughts that lead to anxiety and other symptoms of disorder,* 665–666

Reaction time *The time between the presentation of a stimulus and an overt response to it,* 288

Reading
  memory and, 277–278
  nearsightedness and, 123

Reality principle *The operating principle of the ego that creates compromises between the id's demands and those of the real world,* 559

Reasoning *The process by which people generate and evaluate arguments and reach conclusions about them,* 295
  formal, 295–297
  informal, 297–298
  logical, 295
  moral, 507–508
  quantitative, 377
  symbolic, 308–309

REBT. *See* Rational-emotive behavior therapy

Recall, 255–256

Recency effect *A characteristic of memory in which recall of the last few items in a list is particularly good,* 256

Receptive aprosodia, 825

Receptive field, 124–125

Receptors. *See* Neural receptors

Recessive genes, A6

Reciprocal determinism, 575

Reciprocal teaching, 232

Reciprocity, 730

Reconditioning *The quick relearning of a conditioned response following extinction,* 202

Recovered memory, 267–271

Reduced planfulness, 351

Reference groups *Categories of people to which people compare themselves,* 698

Reflexes *Simple, involuntary, unlearned behaviors directed by the spinal cord without instructions from the brain,* 73, 471

Refractory period *A short rest period between action potentials,* 68

Reinforcement schedules *In operant conditioning, rules that determine how and when certain responses will be reinforced,* 214–215

Reinforcement sensitivity theory, 569–570

Reinforcement *The process through which a particular response is made more likely to recur,* 209
  accidental, 216
  continuous, 214
  delay, size of, 213
  extinction, 215–216
  negative, 209–211, 217, 221
  partial, 214, 216
  positive, 209–210, 212, 221
  primary, 213
  secondary, 213

Reinforcer *A stimulus event that increases the probability that the response that immediately preceded it will occur again,* 208–209

Relatedness needs, 442, 784

Relationship-motivated leader *A leader who provides loose supervision, asks for group members' ideas, and is concerned with subordinates' feelings,* 763

Relative deprivation *The belief that, in comparison to a reference group, one is getting less than is deserved,* 698–699

Relative size, 170–171

Relearning method *A way to measure forgetting by comparing the number of repetitions needed to learn and, after a delay, relearn the same material,* 264

Reliability. *See* Statistical reliability

Reliability Scale, 557

REM behavior disorder *A sleep disorder in which a person does not lose muscle tone during REM sleep, allowing the person to act out dreams,* 348–349

REM sleep. *See* Rapid eye movement sleep

Reminyl, 828

Repetitive strain injuries, 793

Repetitive transcranial magnetic stimulation (rTMS), 682

Repolarization, cell membrane, 68

Representative sampling *A process for selecting research participants whose characteristics fairly reflect the characteristics of the population from which they were drawn,* 46

Representativeness heuristic *A mental shortcut that involves judging whether something belongs in a given class on the basis of its similarity to other members of that class,* 299

Repressed memory *A painful memory that is said to be kept out of consciousness by psychological processes,* 267–271

Research. *See also* Experiment
  critical thinking in, 32–36, 59

Resilience *A quality allowing children to develop normally in spite of severe environmental risk factors,* 500

Resiliency training, 224

Resistance stage, stress response, 529
Resource dilemma, 760
Response criterion *The internal rule a person uses to decide whether or not to report a stimulus,* 163
Response deprivation hypothesis, 217
Reticular activating system (RAS), 816
Reticular formation *A collection of cells and fibers in the hindbrain and midbrain that are involved in arousal and attention,* 80, 816
Retina *The surface at the back of the eye onto which the lens focuses light rays,* 121
  focusing light, 121–122
  light coversion, into images, 123–125
  visual pathways, 126
Retinal disparity *A depth cue based on the difference between two retinal images of the world,* 172–173
Retirement, 515–516
Retrieval cue *A stimulus that aids the recall or recognition of information stored in memory,* 256, 268
Retrieval *The process of recalling information stored in memory,* 242, 249
  brain and, 275–276
  context, state dependence and, 257
  memory construction, 259–261
  retrieval cues, encoding specificity and, 256
  semantic memory, 258–259
Retroactive inhibition *A cause of forgetting in which new information placed in memory interferes with the ability to recall information already in memory,* 265–266
Retrograde amnesia *A loss of memory for events prior to a brain injury,* 274
Retrospective bias, 819
Reuptake, 690

  social skills and, 494–496
Social dilemma *A situation in which actions that produce rewards for one individual will produce negative consequences if adopted by everyone,* 758–760
Social discrimination *Differential treatment of various groups; the behavioral component of prejudice,* 715
Social facilitation *A phenomenon in which the presence of others improves a person's performance,* 731
Social identity *The beliefs we hold about the groups to which we belong,* 700–701
Social impact theory, 735
Social influence *The process whereby one person's behavior is affected by the words or actions of others,* 697–701, 729–730
  aggression and, 743–750
  altruism and helping behavior and, 751–756
  conformity and compliance and, 732–737
  cooperation, competition, and conflict and, 758–762
  deindividuation and, 730, 731
  group processes and, 762–765
  norms and, 733–734
  obedience and, 737–743
Social interference *A reduction in performance due to the presence of other people,* 731
Social loafing *Exerting less effort when performing a group task than when performing the same task alone,* 313, 731–732
Social neuroscience, 713
Social norms *Socially based rules that prescribe what people should or should not do in various situations,* 729–730
Social perception *The processes through which people interpret information about others, draw inferences about them, and develop mental representations of them,* 701
  attribution and, 704–707
  first impressions, 702–704
  schemas and, 701
  self-protective functions and, 707
Social phobia *An anxiety disorder involving strong, irrational fears relating to social situations,* 611
Social psychologists *Psychologists who study how people influence one another's behavior and mental processes, individually and in groups,* 8
Social psychology *The study of how people's thoughts, feelings, and behavior influence and are influenced by the behavior of others,* 8, 697, 713–714
Social Readjustment Rating Scale (SRRS), 527
Social referencing, 459, 484
Social skills, 494–496
Social skills training *A method for teaching clients the behaviors they need in order to interact with others more comfortably and effectively,* 662
Social striving, 732
Social support *The network of friends and social contacts on whom one can depend for help in dealing with stressors,* 537–540
Social-cognitive approach *The view that personality reflects learned patterns of thinking and behavior,* 573
  behavior therapy and, 660
  evaluation of, 576–577
  to mental disorder, 600–601
  to psychology, 22
  roots of, 573–574
  theories of, 574–576
Socialization *The process by which parents, teachers, and others teach children the skills and social norms necessary to be well-functioning members of society,* 491
  gender roles and, 497–498
  observational learning and, 229
  parenting styles and, 491–493
Sociocultural diversity, 24–28
Sociocultural factors *Characteristics or conditions that can influence the appearance and form of maladaptive behavior,* 25, 601
Sociocultural perspective *A way of looking at mental disorders in relation to gender, age, ethnicity, and other social and cultural factors,* 601
Socioeconomic differences, IQ scores and, 386–387
Somatic nervous system *The subsystem of the peripheral nervous system that transmits information from the senses to the central nervous system and carries signals from the central nervous system to the muscles,* 71–72, 106
Somatic senses, 141. *See also* Cutaneous senses
Somatization disorder *A somatoform disorder in which there are numerous physical complaints without verifiable physical illness,* 617
Somatoform disorders *Psychological problems in which symptoms of a physical disorder are present without a physical cause,* 616–618
Somatoform pain disorder *A somatoform disorder marked by complaints of severe pain with no physical cause,* 617
Somatosensory cortex, 87–88
  motor and, 88
  pain and, 144
  touch receptors and, 142–143
Somatosensory strip, 144
Somatosensory systems, 141. *See also* Cutaneous senses
Sound *A repetitive fluctuation in the pressure of a medium, such as air,* 113
  locating, 118–119
  physical characteristics of, 113
  psychological dimensions of, 113–115
Spanking, as punishment, 218
Spatial code, 112
Spatial intelligence, 398
Special K, 364
Specific energy doctrine *The discovery that stimulation of a particular sensory nerve provides codes for that sense, no matter how the stimulation takes place,* 111
Specific hungers, 423
Specific language impairment (SLI), 321
Specific phobia *An anxiety disorder involving fear and avoidance of heights, animals, or other specific stimuli and situations,* 610
SPECT. *See* Single-photon emission computed tomography
Speech, 316
  perceived words, sentences, 316–318
  spectograms, 317
Speech spectrograms, 317
Spinal cord *The part of the central nervous system within the spinal column that relays signals from peripheral senses to the brain and conveys messages from the brain to the rest of the body,* 73–74
  gate control theory of pain, 145–146
  hindbrain, 80
  injury to, 95–96
Split-brain studies, 91–92
Split-half method, 380
Spontaneous generalizations, 260–261
Spontaneous recovery *The reappearance of the conditioned response after extinction and without further pairings of the conditioned and unconditioned stimuli,* 202–203, 236
Sport psychologists *Psychologists who explore the relationships between athletic performance and such psychological variables as motivation and emotion,* 9
Spreading activation *A principle that explains how information is retrieved in semantic network theories of memory,* 258

SRRS. *See* Social Readjustment Rating Scale
SSRIs. *See* Selective serotonin reuptake inhibitors
Standard deviation (SD) *A measure of variability that is the average difference between each score and the mean of the data set,* A14–A15
Standard scores *Values that indicate the distance, in standard deviations, between a given score and the mean of all the scores in a data set,* A16
Stanford-Binet Intelligence Scale *A test for determining a person's intelligence quotient, or IQ,* 375
Stapes, in ear structure, 115
State theories of hypnosis *Theories proposing that hypnosis is an altered state of consciousness,* 352
State-dependent memory (state-dependent learning) *Memory that is aided or impeded by a person's internal state,* 257
Statistical analysis, A13
  critical thinking and, 55–57
  descriptive statistics, 51–55, 60, A13, A14
  inferential statistics, 55, 60, A13, A17
Statistical infrequency, 597
Statistical reliability (reliability) *The degree to which test results or other research evidence occurs repeatedly,* 35, 379–380
Statistical significance *Referring to a correlation, or a difference between two groups, that is larger than would be expected by chance,* 55, 674
Statistical validity (validity) *The degree to which evidence from a test or other research method measures what it is supposed to measure,* 35, 380–381
Statistics, psychological research, A13
  correlation, A16–A17
  describing data, A13
  descriptive, A14
  histogram, A13–A14
  inferential, A17
  measures of central tendency, A14
  measures of variability, A14–A15
  N, A14
  normal distribution, A15–A16
  t test, A17–A19
Stepping reflex, 472
Stereotype *A false assumption that all members of some group share the same characteristics,* 714–716
Stereotype threat, 383–384
Steven's power law, 166
Stimuli, 198–200
Stimulus control, 211, 220, 347
Stimulus discrimination *A process through which individuals learn to differentiate among similar stimuli and respond appropriately to each one,* 203, 207, 211–212, 236
Stimulus generalization *A phenomenon in which a conditioned response is elicited by stimuli that are similar but not identical to the conditioned stimulus,* 203, 207, 211–212, 236
Stimulus-response compatibility, 288
Stirrup, in ear structure, 115
STM. *See* Short-term memory
Storage *The process of maintaining information in memory over time,* 242
  long-term memory, 253–256
  sensory memory, 249–250
  short-term memory, 250–253, 255–256
Strange Situation, 487
Stress inoculation training, 666
Stress mediators, 534
  appraising stressors, 534–535
  coping resources and methods, 536–537, 550–552
  personality, gender and, 540–543
  predictability and control, 535–536
  social support, 537–540
Stress reactions *The physical, psychological, and behavioral response that occurs in the face of a stressor,* 525
Stress responses, 527–528
  cognitive influences on, 535
  physical, 528–530
  psychological, 530–532
Stress *The internal processes that occur as people try to adjust to events and situations, especially those that they perceive to be beyond their coping capacity,* 525
  aggression and, 527, 532
  alcohol and, 532, 536, 551
  ANS and, 528–529, 544, 613
  anxiety and, 531, 533–534
  arousal and, 531, 534, 538
  attention and, 531
  cardiovascular system and, 545–547
  cognition and, 530–532
  coping with, 550–552
  depression and, 534, 539
  gender and, 540–541
  helping behavior and, 754
  illness and, 543–547
  immune system and, 543–545
  mediators of, 525, 534–543
  meditation and, 354–355
  memory and, 544–545
  motivational conflicts and, 443–444
  obesity and, 426
  personality and, 540
  prenatal risks and, 469
  problem solving and, 550
  process of, 525
  psychological disorders and, 532–533
  somatoform disorders and, 616–617
  in workplace, 795
Stressors *Events or situations to which people must adjust,* 525
  measuring, 526–527
  psychological, 526
Striatum *A structure within the forebrain that is involved in the smooth beginning of movement,* 81–82
Striving for superiority, 562
Stroboscopic illusion *An illusion of motion that is created when we see slightly different images or slightly displaced lights flashed in rapid succession,* 174
Stroop Color Word Test, 189
Structural family therapy, 670
Structuralism, 14–15
Structured interview, 773
Studying, memory improvement and, 276–279
Subconscious, 334
Subculture, 26
Subjective contours, 167
Subjective measures, of job performance, 775–777
Subjective norms, 708
Subjective well-being, 440
Subliminal advertising, 161–162
Subliminal messages, in music, 336–338
Subliminal priming, 161
Subliminal stimulation *Stimulation that is too weak or brief to be perceived,* 160–162
Substance abuse, 355–357
Substance abuse counselors, 652
Substance-related disorders *Problems involving the use of psychoactive drugs for months or years in ways that harm the user or others,* 640–641
  alcoholism, 641–642
  cocaine, 642–643
  heroin, 642–643
Substantia nigra *An area of the midbrain involved in the smooth beginning of movement,* 81–82
Subtraction technique, 302
Subtractive color mixing, 129
Successive approximations, 212
Sudden infant death syndrome (SIDS) *A disorder in which a sleeping baby stops breathing and suffocates,* 348
Suicide
  in adolescence, 501
  depression and, 621–623
  ethnic group differences, 622
  gender and, 622
Sulci, 87
Superego *The component of personality that tells people what they should and should not do,* 559
Superordinate goals, 762
Superordinate identity, 762
Superstition, 216
Supertasters, 139–140

Suprachiasmatic nuclei (SCN), 344
Suprachiasmatic nuclei *Nuclei in the hypothalamus that generate biological rhythms,* 82
Supraliminal stimulation *Stimulation that is strong enough to be consistently perceived,* 160
Surface structure *The order in which words are arranged in sentences,* 316
Survey *A research method that involves giving people questionnaires or special interviews designed to obtain descriptions of their attitudes, beliefs, opinions, and intentions,* 39–41, 59–60
Surviving Babylon (Garson), 269
Survivor (television), 759
Syllogism *An argument made up of two propositions, called premises, and a conclusion based on those premises,* 296
Symbolic reasoning, 308–309
Sympathetic nervous system *The subsystem of the autonomic nervous system that usually prepares the organism for vigorous activity,* 72, 448
Sympatho-adreno-medullary (SAM) system, 528, 545
Synapses *The tiny gaps between neurons across which they communicate,* 66, 272
Synaptic gaps, 66. *See also* Synapses
Synchrony, in perceptual grouping, 169
Syndrome *A pattern of symptoms associated with a specific disorder,* 813
Synesthesia *A blending of sensory experience that causes some people to "see" sounds or "taste" colors, for example,* 133–135
Syntax *The set of rules that govern the formation of phrases and sentences in a language,* 315
Systematic desensitization therapy *A behavioral treatment for anxiety in which clients visualize a graduated series of anxiety-provoking stimuli while remaining relaxed,* 661–662

t table, A18–A19
t test, A17–A19
Tabula rasa, 14
Tangles, in neurons, 84
Tardive dyskinesia (TD), 683
Target organs, 103, 448
Task-motivated leader *A leader who provides close supervision, leads by directives, and generally discourages group discussion,* 763
Taste
  aversions, 205
  smell, flavor and, 139–140, 140–141
Taste buds, 139
Taste perception *The sense of taste,* 135
TAT. *See* Thematic Apperception Test
Tau protein, 84
TCAs. *See* Tricyclic antidepressants
T-cells, 544
TD. *See* Tardive dyskinesia
Telegraphic stage, in language development, 320
Television, violence and, 229–231
Temperament *An individual's basic disposition, which is evident from infancy,* 484–486, 583–585
Temperature
  aggression and, 151, 154, 750
  flavor of food and, 140
  touch and, 141–143
Temporal code, 112
Temporal comparison, 698
Teratogens *Harmful substances that can cause birth defects,* 469
Terman Life Cycle Study of Intelligence, 541–542
Terminal drop *A sharp decline in mental functioning that tends to occur in late adulthood, a few years or months before death,* 516
Terror management theory, 699–700
Test *A systematic procedure for observing behavior in a standard situation and describing it with the help of a numerical scale or a category system,* 379
  measuring quality of, 379
  statistical reliability, 379–380
  statistical validity, 380–381
Test anxiety, 383
Testes, 103
Testosterone, 103, 430, 744–745
Test-retest reliability, 379
Tetrahydrocannabinol (THC), 364
Texture, in perceptual grouping, 168
Thalamus *A forebrain structure that relays signals from most sense organs to higher levels in the brain and plays an important role in processing and making sense out of this information,* 82–83
  memory and, 272–273, 275
  pain pathways, 144
  sensory systems and, 111, 112, 117, 126
Thanatos, 559
THC. *See* Tetrahydrocannabinol
Thematic Apperception Test (TAT), 437, 586
Theoretical criterion, 774–775
Theory *An integrated set of propositions that can be used to account for, predict, and even suggest ways of controlling certain phenomena,* 35–36
Therapist, 651–652
Thinking *The manipulation of mental representations,* 287
  adolescence, changes in, 500–501
  basic functions of, 285
  circle of, 286–288
  critically, 32–35
  decision making and, 309–314
  development of, 7
  information-processing and, 287–290
  language and, 314–326
  mental representations in, 290–295
  problem solving and, 300–309
  strategies for, 295–300
Third-party interventions, 762
Thorazine, 683
Timbre *The mixture of frequencies and amplitudes that make up the quality of sound,* 115
Time out, 663
Tinnitus, 151
Tip-of-the-tongue phenomenon, 259
Tit-for-tat, 760
Token economy programs *Systems for improving the behavior of institutionalized clients in which desirable behaviors are rewarded with tokens that can be exchanged for desired items or activities,* 662
Top-down processing *Aspects of recognition that are guided by higher-level cognitive processes and psychological factors such as expectations,* 177, 179–180, 182, 194, 317–318
Topographical representations, 112
Touch, 141, 151
  encoding, information and, 142–143, 153
  receptors, adaptation of, 142
  stimulus, receptors and, 141–142
  temperature and, 143, 154
"Toward Neuroanatomical Models of Analogy: A Positron Emission Tomography Study of Analogical Mapping" (Wharton), 302
Traffic safety, perception factors in, 191–192, 194
Trainee learning criteria, 782–783
Training in general principles, 781
Training needs assessment, 780–781
Training-level criteria, 782
Trait approach *The view that personality is a combination of characteristics that people display over time and across situations,* 564–565
  Allport's trait theory, 566–567
  biological trait theories, 568–570
  evaluation of, 572–573
  five-factor personality model, 567–568
  traits *vs.* types, 565–566
Tranquilizing drugs (anxiolytics) *Drugs that reduce feelings of anxiety,* 685, 745
Transactional leader, 763
Transcranial magnetic stimulation (TMS), 74, 76, 79
Transduction *The process of converting incoming energy into neural activity,* 110
Transfer of training, 781
Transfer-appropriate processing model of memory *A model that suggests that a critical determinant of memory is how*

well the retrieval process matches the original encoding process, 246
Transference, 654–655
Transformational leader, 763
Traumatic brain injury (trauma) *An impact on the brain caused by a blow or a sudden, violent movement of the head,* 812–813
Traveling wave theory, 119
Treatment, 651
  basic features of, 651–653
  behavior therapy, 659–667
  biological, 681–690
  community psychology, 690–692
  group, family, and couples therapy, 667–671
  humanistic psychotherapy, 656–659
  psychodynamic psychotherapy, 653–656
  psychotherapy evaluation, 671–681
Triangular theory, of love, 722
Triarchic theory of intelligence *Robert Sternberg's theory that describes intelligence as having analytic, creative, and practical dimensions,* 396–398
Trichromatic theory *A theory of color vision identifying three types of visual elements, each of which is most sensitive to different wavelengths of light,* 129–131
Tricyclic antidepressants (TCAs), 684
Tryptophan, 100
Turnover, job satisfaction and, 790–791
Twin studies
  alcoholism, 642
  anxiety disorders, 613
  behavioral genetics, 47–50
  bipolar disorders and, 624
  IQ and, 384–385, A8–A9
  job satisfaction and, 788–790
  schizophrenia and, 631, A10
  sexual orientation and, 433–434
Two-dimensional location, 170
Tympanic membrane *A membrane in the middle ear that generates vibrations that match the sound waves striking it,* 115
Type A behavior, 546

UCR. *See* Unconditioned response
UCS. *See* Unconditioned stimulus
Ultimate attribution error, 706
Umami, 139
Umbilical cord, 468
Unambiguity, conformity and, 735
Unconditional positive regard (acceptance) *A therapist attitude that conveys caring for and acceptance of the client as a valued person,* 657
Unconditioned response (UCR) *The automatic or unlearned reaction to a stimulus,* 202, 236
Unconditioned stimulus (UCS) *A stimulus that elicits a response without conditioning,* 201–205, 201–236
Unconscious level *A level of mental activity that influences consciousness but is not conscious,* 334
Uniform Guidelines on Employee Selection Procedures, 780
Uninvolved (rejecting-neglecting) parents *Parents who are indifferent to their children,* 491–492
Unrealistic optimism, 707
Unstructured interview, 773
Upward social comparison, 698
Utility *A subjective measure of value,* 310

Validation *In I/O psychology, the effort to determine how well a test, interview, or other assessment method predicts job performance,* 779
Validity. *See* Statistical validity
Valium, 685
Variability, measures of, 53, A14–A15
Variable-interval (VI) reinforcement *A partial reinforcement schedule that provides reinforcement for the first response after varying periods of time,* 214
Variable-ratio (VR) reinforcement *A partial reinforcement schedule that provides reinforcement after a varying number of responses,* 214
Vascular dementia *A form of dementia caused by multiple restrictions of the brain's blood supply,* 827–828
Venlafaxine, 684
Ventromedial nucleus, 422
Vesicles, 68
Vestibular sacs *Organs in the inner ear that connect the semicircular canals and the cochlea and contribute to the body's sense of balance,* 150
Vestibular sense, 150. *See also* Sense of equilibrium
Vestibular-ocular reflexes, 150
Vicarious experience *Conditions that allow us to learn by watching what happens to others,* 229
Video games, aggression and, 746–748
Violence
  in adolescence, 504
  television and, 229–231
Virtual reality system, 233
Visible light *Electromagnetic radiation that has a wavelength of approximately 400 to 750 nm,* 121
Vision, 120
  color, seeing, 129–133, 154
  focusing light, 121–122, 154
  light, 121, 154
  light conversion, to images, 123–125, 154
  visual pathways, 126, 154
  visual representations, 126–129, 154
Visual acuity *Visual clarity, which is greatest in the fovea because of its large concentration of cones,* 124
Visual agnosia, 807, 820
Visual cliff, 184
Visual cortex *An area at the back of the brain to which neurons in the lateral geniculate nucleus relay visual input,* 87, 126
Visual encoding, 242
Visual memory *The mental representation of information as images,* 242
Visual pathways, 126
Visual receptive field *The portion of the retina, and the visual world, that affects a given ganglion cell,* 124
Visual representations, 126
  hierarchical processing, of visual information, 128–129
  parallel processing systems, 126–128
Visual-spatial processing, 377
Volley theory *The view that some sounds are coded by matching the frequency of neural firing,* 120
Voluntary movements, 825
Vomeronasal system *A portion of the mammalian olfactory system that is sensitive to pheromones,* 137, 137–138
Vulnerability theory, 632–633

Wada test, 818
WAIS IV. *See* Wechsler Adult Intelligence Scale
Wave, sound, 113–114
Waveform, sound, 113–114
Wavelength *The distance from one peak to the next in a waveform,* 113
  color sensations and, 129–131
  trichromatic theory, 129–131
Waxy flexibility, 629
Weber's constant (K), 165
Weber's fraction (K), 165
Weber's law *A law stating that the smallest detectable difference in stimulus energy is a constant fraction of the intensity of the stimulus,* 165
Wechsler Adult Intelligence Scale (WAIS IV), 376, 810
Wechsler Intelligence Scale for Children (WISC-IV), 376–377
Well-being *A combination of a cognitive judgment of satisfaction with life, the frequent experiencing of positive moods and emotions, and the relatively infrequent experiencing of unpleasant moods and emotions; also known as subjective well-being,* 440–441
Wellbutrin, 684
Wernicke-Geschwind model, of aphasia, 824

Wernicke's aphasia *A language disorder in which there is a loss of ability to understand written or spoken language and to produce sensible speech,* 824
Wernicke's area, 90, 824
White-coat hypertensives, 206
Williams syndrome, 406
WISC-IV. *See* Wechsler Intelligence Scale for Children
Wish fulfillment, 349
Withdrawal symptoms, 641
Withdrawal syndrome, 356
Womb envy, 562
Wonderlic Personnel Test, 378
Woodcock-Johnson Psychoeducational Battery, 377
Word salad, 628
Word superiority effect, 180
Work group *Two or more people who interact as they perform workplace tasks,* 795–796
  autonomous, 796–797
  leadership, 797–800
Work shifts, 794–795
Work team *A work group in which the members' specialized activities are coordinated and interdependent as they work toward a common goal,* 795–796
Work-family conflict, 787–788
Working backward, 301
Working memory *The part of the memory system that allows us to mentally work with, or manipulate, information being held in short-term memory,* 250, 256, 272, 274, 297, 377
Workplace
  achievement motivation and, 439–440
  aggression and, 791–792
  stress and, 795

Xanax, 685, 689
Yerkes-Dodson law, 419
Yin and yang, 599

Zero-sum game *A social situation in which one person's gains are subtracted from another person's resources so that the sum of the gains and losses is zero,* 761
Ziprasidone, 683
Zoloft, 100, 684, 685
Zygote *A new cell, formed from a father's sperm and a mother's ovum,* 468, A6
Zyprexa, 683

Applications of Psychology In the Real World

Psychological science is used by real people, in real situations, every day. Applied psychology is emphasized throughout the 9th edition of *Psychology*, along with a strong focus on basic research. Research and applications are closely integrated throughout the book. For example:

Chapter 1:

- **Human factors** psychologists improve product design. (page 5)
- **Health psychology** helps patients prepare mentally for surgical procedures, so they'll be less stressed and recover more rapidly. (page 6)
- **Social psychologists'** research on interpersonal attraction is used by some commercial matchmaking services to pair up people who are most likely to be compatible. (page 8)
- **Forensic psychologists** profile criminals, evaluate the mental competence of defendants, participate in jury selection, and perform many other tasks related to psychology and the law. (page 9)
- **Cognitive psychologists'** research on the quirks of human memory has led to revised guidelines for police and prosecutors to prevent distorting the memories of witnesses and reduce false accusations. (page 10)

Chapter 2

- **Psychologists evaluate claims in the real world**, such as the common fear that exposure to microwave radiation from cell phone antennas may cause brain tumors, whether the dangers of hormone replacement therapy (HRT) for postmenopausal women outweigh its benefits, and questions about the value of herbal remedies, dietary supplements, and other controversial treatments for cancer, AIDS, and depression. (page 34)
- **Human factors psychologists and industrial and organizational psychologists design better work environments** by observing people at work to see what they do, how they do it, and how they interact with machines and fellow employees. (page 38)
- **Psychologists protect the welfare** of animal participants in research. (page 57)

Chapter 3

- **Problems in the nervous system** can cause problems with mobility and sensation. (page 70)
- **Psychologists employ techniques** such as EEG, PET scanning, MRI, and TMS for studying the human brain. (page 75)
- **Field sobriety tests** have been developed to detect impairment in the cerebellum. (page 82)
- **Research with animals helps develop new techniques** for the detection and treatment of diseases. (page 86)
- **Psychologists develop prosthetic limbs** using information from studies of the nervous system. (page 89)
- **The difficulty of multitasking** is explained by studies of how the brain functions. (page 91)
- **Psychologists help develop better programs to help recovery from spinal cord injuries** through research on neurogenesis, neural plasticity, and physical therapy. (page 96)

Chapter 4

- **Noise-canceling headphone technology** is based on psychological research about sensation. (page 113)
- **Psychologists help develop new treatments for certain types of deafness** through research on the biological aspects of hearing. (page 116)
- **Psychophysical research on sight helps artists and lighting designers** understand how to mix colors. (page 129)
- **Psychologists help people understand and control their pain.** (page 145)

Chapter 5

- **Psychological research has shown that subliminal advertising is considerably less effective** than some marketers would like to believe. (page 161)
- **Improving the ability of weather forecasters to predict tornadoes and alert the public** is an important part of signal detection theory. (page 164)
- **Psychologists help design better road signs and signals** through research on visual perception. (page 176)
- **Psychologists' research on perception helps increase aviation safety and pilot effectiveness.** (page 190)
- **Engineering psychologists help design computer hardware and software that's easier to use and understand.** (page 190)
- **Human factors psychologists help reduce automobile accidents** by designing better gauges and instruments, controls that are easier to use, and pavement markings that are easier to understand. (page 191)
- **Cognitive psychologists are helping to reduce distracted driving** through research on divided attention and the use of cell phones, texting devices, and other demands on drivers' attention. (page 192)

Chapter 6

- **Psychologists help save the lives of children with dangerous disorders** through the use of appropriate punishment techniques. (page 219)
- **Filmmakers use psychological research on sensitization** to make their films scarier or more tense. (page 199)
- **People with phobias learn to overcome their fears** through the use of systematic desensitization. (page 206)
- **Insects can be trained to detect explosives and other dangerous or illegal substances** through the use of classical conditioning. (page 206)
- **Scientists have developed successful wildlife control efforts to protect people and livestock**, through the use of classical conditioning. (page 207)
- **People teach their pets tricks and other new behaviors** through operant conditioning. (page 208)
- **Teachers and parents motivate children's achievement** using secondary reinforcers. (page 213)
- **Professors encourage class participation** with shaping techniques. (page 220)
- **People with drug addictions or other problematic behaviors can learn to develop more healthy lifestyles** using operant conditioning techniques such as reinforcement, punishment, and stimulus control. (page 220)
- **Children's achievement in school is enhanced through reciprocal teaching.** (page 232)
- **Active learning techniques help make teaching and learning much more effective.** (page 233)
- **Medical students perfect their surgical techniques on virtual patients, and hone their diagnostic skills on simulators**, becoming more experienced and confident, before they deal with actual patients. (page 233)
- **Coaches learn appropriate feedback techniques** to help budding athletes achieve their fullest potential. (page 234)

Chapter 7

- **Students can maximize their ability to recall information for an examination** if they know what kind of test will be given and study appropriately. (page 246)
- **Courts have realized that how attorneys ask a question may influence eyewitness accounts**, thanks to psychologists' research on memory. (page 262)
- **People can remember things they thought they had forgotten by using appropriate memory cues** such as going to particular places or looking at specific objects. (page 257)
- **Police have changed the way in which they conduct lineups** after learning more about how their old methods might have created memory errors. (page 263)
- **People can improve their memories by getting more sleep**. (page 266)

- **Students can increase their learning efficiency and ability to remember what they've studied**, using mnemonic strategies suggested by memory researchers. (page 278)

Chapter 8

- **People can learn to avoid many errors in judgment and problem solving** thanks to the work of cognitive psychologists. (page 290)
- **Artificial intelligence systems can be used to help doctors and laboratory technicians make better medical decisions.** (page 309)
- **Economists can better understand why people take the risks they do** because of research on decision-making and cognitive processing. (page 311)
- **Decision-making groups can avoid groupthink and social loafing** because of group strategies suggested by social psychologists. (page 313)
- **Work groups that use computer-mediated communication technologies can be as effective as groups that meet face-to-face,** thanks to work by cognitive psychologists. (page 313)
- **Teaching children to communicate in more than one language** right from the beginning can enhance their creativity and thinking skills. (page 312)

Chapter 9

- **Psychologists have found ways to help alleviate the effects of jet lag.** (page 344)
- **New Jersey has expanded the definition of reckless driving to include "driving while fatigued"** based on psychologists' research about sleep deprivation. (page 345)
- **Insomnia can often be reduced** through a combination of cognitive behavior therapy, relaxation techniques, and stimulus control therapy, in which the person goes to bed only when sleepy and gets out of bed if sleep does not come within fifteen to twenty minutes. (page 347)
- **Hypnosis may be used during surgery**, when patients cannot tolerate the use of anesthetics, and to alleviate many medical conditions. (page 353)
- **Psychological research shows that meditation can be used to alleviate stress.** (page 354)
- **Psychologists have helped to provide new treatments for people who want to give up smoking.** (page 362)

Chapter 10

- **Psychologists have developed tests for many kinds of intelligence**, beyond the IQ tests. (page 377)
- **Psychological research suggests that people's performance on certain cognitive tests can be affected by empowering or discouraging messages about their abilities.** (page 384)
- **Efforts such as Project Head Start can help pre-school children improve their chances of academic success.** (page 389)

Chapter 11

- **People tend to eat less or more depending on how the people around them are eating.** (page 424)
- **Some fashion shows have now established a certain minimum BMI for all models**, to combat the problems caused by unhealthy dieting. (page 427)
- **One of the most effective options for losing weight is a change of lifestyle** which includes changes in eating habits, exercise patterns, and other behaviors. (page 427)
- **It is possible to enhance people's achievement motivation**, not only through childhood training, but even later in life. (page 437)
- **Many U.S. companies have redesigned jobs to increase workers' responsibility and flexibility**, which increases productivity and job satisfaction by creating teams in which employees are responsible for solving production problems and making decisions about how best to do their jobs. (page 440)

Chapter 12

- **Appropriate stimulation is necessary for babies' normal cognitive and emotional development**. (page 482)
- **Some employers provide on-site day care or allow employees to keep their babies in their offices while working,** to help parents build attachments with their infants. (page 489)
- **Research on how parenting styles affect children's behavior has helped shape parent-training programs** based on learning principles and on the social-cognitive and humanistic approaches to personality. These programs teach authoritative parenting methods. (page 492)
- **People tend to behave more morally when they feel as though they are being watched.** This seems to be true even when they are only being watched by a poster showing human eyes watching the room. (page 507)
- **Adolescents find that online communication with friends enhances both their friendships and their sense of well-being.** While some early studies created concern that intense Internet use might have negative long-term effects on adolescent texters' ability to plan, think flexibly and abstractly, learn rules, inhibit inappropriate actions, and focus on relevant information, more recent research suggests that these concerns may be exaggerated. (page 502)
- **Keeping mentally active and finding new challenges as we age can keep people cognitively and psychologically flexible well into older adulthood.** It's important to keep up activities such as doing puzzles, painting, and talking to intelligent friends. Aerobic exercise can also contribute to longer psychological health. (page 511)

Chapter 13

- **Health psychologists have developed programs to help people increase exercise, stop smoking, eat healthier diets, and make other lifestyle changes that can lower their risk of illness and death**. They have even helped bolster community blood supplies by finding ways to make blood donation less stressful. (page 524)
- **Health care psychologists provide on-the-spot counseling and follow-up sessions to help people deal with the consequences of trauma**, such as earthquakes, explosions, hurricanes, plane crashes, and school shootings. (page 526)
- **Psychological factors have a tremendous impact on immune system functioning.** Openly expressing emotions, collaborating closely with doctors, having optimistic expectations, remaining involved in normal activities, finding meaning in the situation, and other active, problem-focused coping strategies all have been associated with slower progression of HIV/AIDS. (page 539)

Chapter 14

- **Positive Psychology has helped to focus attention on human character strengths** such as wisdom, courage, and humanity. It focuses on happiness, thriving, and other aspects of human experience associated with maximum personal development and functioning (page 578)
- **Attorneys often consult psychologists when evaluating potential jurors**. These forensic psychologists employ type and trait theories of personality to determine which potential jurors are most likely to be sympathetic to their side in a court case. (page 565)
- **Personality tests are used to predict many different types of behaviors.** These include success in business, performance in specific jobs, and the likelihood of engaging in criminal behavior or risky sexual behavior. (page 588)

Chapter 15

- **Fear and Fearlessness can be learned vicariously.** By simply watching a calm boy in a dental chair, another other youngster may learn to relax with his dentist. (page 614)
- **Seasonal affective disorder (SAD) can often be relieved by exposure to full-spectrum light for as little as a couple of hours a day.** (page 625)
- **People who have severe psychological disorders are protected from prosecution under certain circumstances.** (page 643)

Chapter 16

- **Empirically supported therapies** are approaches to psychological treatment that have been found both efficacious and specific by researchers and practitioners. (page 675)
- **Many conditions can be alleviated using psychoactive drugs.** (page 686)
- **Participant modeling is a successful method for treating phobias.** (page 663)

Continued

Applications of Psychology In the Real World *(continued)*

Entries that appear in blue refer to the optional Industrial and Organizational Psychology or Neuropsychology chapters.

- **Patients can begin to combat their phobias using virtual reality systems,** rather than immediately confronting their fears in real situations. (page 661)
- **Flooding is a relatively quick, effective treatment for specific phobias**. (page 664)
- **Special pretreatment orientation programs may be offered to clients** who are unfamiliar with the rules and procedures of psychotherapy. These programs provide a preview of what psychotherapy is, how it can help, and what the client is expected to do to make it more effective. (page 679)
- **Professional and nonprofessional staff members of community mental health centers provide traditional therapy and mental health education, along with walk-in facilities and hotlines for people who are suicidal or in crises because of rape or domestic violence.** They also offer day treatment to former mental patients, many of whom are homeless. (page 691)

Chapter 17

- **Many charities and educational groups use photographs of people in need** to evoke the emotions of potential donors. (page 709)
- **Cooperative contact between people of different ethnic groups can promote mutual respect and reduce ethnic prejudice.** (page 717)
- **Advertisers and others who wish to persuade people to make certain decisions can use the mere-exposure effect to sway people to their point of view.** (page 710)
- **One way to strengthen a relationship is to strengthen the patterns of communication between partners.** (page 724)

Chapter 18

- **Hotels can make guests more likely to re-use their towels and recycle their newspapers by using descriptive norms.** They give specific information about how other people actually behave in a given situation. There is evidence, for example, that how much college students use tobacco and alcohol is influenced both by how much they think other students drink and smoke. (page 730)
- **Supporters of various causes know that people who comply with a small request, such as signing a petition, are the best ones to contact later with requests to do more.** Complying with larger requests is made more likely because it is consistent with the signer's initial commitment to the cause. (page 736)
- **The door-in-the-face technique is sometimes used successfully by teenagers to influence parents to comply with many kinds of requests.** After asking to stay out overnight, a youngster whose curfew is normally 11 p.m. might be allowed to stay out until 1 a.m.—a "compromise" that was actually the original goal. (page 737)
- **Salespeople often use the low-ball technique to get people to buy things at a higher price than the customers originally intended.** First, the salesperson obtains a person's oral commitment to purchase the item at a certain price. Once this commitment is made, the cost of fulfilling increases, perhaps due to an "error" in calculating the price. (page 737)
- **The military and other organizations use the proximity principle to enhance obedience to authority.** Consistent with Milgram's research on obedience, they ensure that no one is ever far away from the authority of a higher-ranking person. (page 740)
- **Psychologists working with architects to design prisons that minimize the sense of crowding may help prevent some of the violence that endangers staff and prisoners.** (page 750)
- **You can get a more intense reaction from your romantic partner, or a more aggressive reaction from someone you bump into, if they've been exercising right before you see them,** because physiological arousal from one experience may carry over to an independent situation, producing what is called *excitation transfer.* (page 749)
- **Evidence from computer simulation studies shows that societies whose members use cooperative strategis with one another are more likely to survive and prosper than are societies whose members act competitively.** (page 759)
- **Communication is key to reducing conflict and increasing cooperation.** (page 760)
- **Researchers have worked on developing techniques to help organizations avoid groupthink.** One way is to teach group members to imagine all the negative outcomes of each course of action they are considering. Another is to designate someone to take the unpopular role of "devil's advocate"—to constantly challenge the group's emerging consensus and offer additional alternatives. (page 764)

Chapter 19

- **Industrial and organizational psychologists helped the U.S. government create its Uniform Guidelines on Employee Selection Procedures**, a document that outlines the steps organizations must take to assure fairness in hiring and promotion. (page 780)
- **Employee training programs help workers who portray cartoon characters at theme parks understand why it is important to remain in character at all times.** They emphasize the general principle that the organization's goal is to create a fantasy world for customers. (page 781)
- **To help working couples deal with both job demands and family obligations, many organizations have adopted family-friendly programs and policies**, including workplace day-care services and the availability of flexible work schedules (flextime). These programs and policies have been associated with higher levels of job satisfaction and less absenteeism among employees with children. (page 787)
- **I/O and engineering psychologists help to develop improved wrist support for keyboard users to prevent repetitive strain injuries.** These would otherwise result from performing the same movements on the job hour after hour and day after day. (page 793)
- **I/O psychologists' research on the negative impact of extended work shifts has led to organizational and U.S. government rules requiring rest breaks at fixed intervals for commercial airline pilots, long-haul bus and truck drivers, and others whose jobs require constant attention to complex tasks and systems.** These rules also limit the total number of hours these employees can work in any twenty-four-hour period. (page 794)

Chapter 20

- **By giving many different tests, the clinical neuropsychologist can get a glimpse into many different aspects of a person's psychological functioning and also measure each area separately.** Analyzing the overall pattern of results may help to pinpoint where the difficulties in the brain may lie. (page 805)
- **New medications can stop or slow the progression of certain dementias.** Drugs such as dimebolin (Dimebon), galantamine (Reminyl), and rivastignime (Exelon) were shown to be somewhat effective at slowing the progress of Alzheimer's disease. Certain antidepressant medications may have similar benefits, and antipsychotic drugs such as risperidone have shown potential for treating some of the behavioral and psychological symptoms of Alzheimer's disease. (page 828)

Education is not a commodity.

reflects **our commitment** to you
and your students:

CENTERING ON Value

BBC Motion Gallery, ABC® videos, PowerLecture™ for easy lecture preparation, and other teaching and learning supplements are available to enhance your course.

CENTERING ON Choice

Choose the format that best suits the needs of you and your students:

- Cengage Learning Advantage Edition (loose-leaf format)
- Cengage Learning eBook
- Chapter-by-chapter purchase
- Textbook rental

CENTERING ON Engagement

Innovative, interactive media resources such as **CengageNOW™, PsykTrek™ 3.0,** and **CourseMate** engage students in the excitement of psychology.

WADSWORTH
CENGAGE Learning™

Cengage Learning
providing the **best content a**
you deserve, in the f

Content Accessibility

Get the content you value in the format you want.

Save up to 60%

In addition to casebound or paperbound format, many titles are offered in alternate, money-saving formats **(30-60% off),** such as:

- Rental
- Loose-Leaf
- Compact Editions
- Black-and-white
- eTextbooks
- eChapters
- Audiobooks

Custom Solutions

Tailor content to fit your course.

It's now **simpler** than ever to create your perfect customized learning **solution** drawing from Cengage Learning's breadth of content and depth of **services** providing **sophisticated results** for you, your students and your course.

Enrichment Modules: Consider adding enrichment content to your text or digital solution to expand coverage on special topics. Some popular module options are Career and Study Skills.

Presets: Our Preset options provide alternate print and digital variations of traditional titles and are created based upon popular custom options that typically include a supplement or enrichment content bound into the book or included in the digital solution.

Textchoice: Our online digital library allows you to build your own custom version of a text as well as incorporate readings, cases, exercises, and other resources into your printed course solution.

www.textchoice.com

is committed to vailable, with the support format you choose.

Learning Solutions – Training & Support

We're your partner in the classroom – online and off.

CengageCourse

CengageCourse delivers dynamic, interactive ways to teach and learn using relevant, engaging content with an accent on flexibility and reliability. When you select the **CengageCourse** solution that matches your needs, you'll discover ease and efficiency in teaching and course management.

CourseCare

CourseCare is a revolutionary program providing you with exceptional services and support to integrate your Cengage Learning Digital Solution into your course. Our dedicated team of digital solutions experts will partner with you to design and implement a program built around your course needs. We offer in-depth, one-on-one professional training of our programs and access to a 24/7 Technical Support website. **CourseCare** provides one-on-one service every step of the way—from finding the right solution for your course to training to ongoing support—helping you to drive student engagement.

TEAM up

For more than a decade, **TeamUP Faculty Programs** have helped faculty reach and engage students through peer-to-peer consultations, workshops, and professional development conferences. Our team of **Faculty Programs Consultants and Faculty Advisors** provide implementation training and professional development opportunities customized to your needs.

Access, Rent, Save, and Engage.

Save up to 60%

CENGAGE brain .com

At CengageBrain.com students will be able to **save up to 60%** on their course materials through our full spectrum of options. Students will have the option to **Rent** their textbooks, purchase print **textbooks, eTextbooks,** or individual **eChapters** and **Audio Books** all for substantial savings over average retail prices.

CengageBrain.com also includes single sign-on access to Cengage Learning's broad range of homework and study tools, and features a selection of free content.
